THE JOURNAL OF

The Institution of Electrical Engineers

ORIGINALLY

The Society of Telegraph Engineers

FOUNDED 1871

INCORPORATED BY ROYAL CHARTER 1921

EDITED BY P. F. ROWELL, SECRETARY.

SAVOY PLACE, VICTORIA EMBANKMENT, LONDON, W.C. 2.

VOL. 68, 1930.

E. AND F. N. SPON, LIMITED, 57, HAYMARKET, LONDON, S.W. 1
SPON AND CHAMBERLAIN, 120, LIBERTY STREET, NEW YORK
1930

UNIV. OF MINN. LIBRARY

The Institution of Electrical Engineers.

VICTORIA EMBANKMENT, LONDON, W.C. 2.

FOUNDED 1871.

INCORPORATED BY ROYAL CHARTER 1921.

Patron: HIS MAJESTY KING GEORGE V.

COUNCIL, 1929-1930.

President.

COLONEL SIR THOMAS F. PURVES, O.B.E.

Past-Presidents.

COLONEL R. E. CROMPTON, C.B.—1895 & 1908.
JAMES SWINBURNE, F.R.S.—1902.
SIR R. T. GLAZEBROOK, K.C.B., D.Sc., F.R.S.—1906.
W. M. MORDEY.—1908.
SIR JOHN SNELL, G.B.E.—1914.
CHARLES P. SPARKS, C.B.E.—1915 & 1916.
ROGER T. SMITH.—1919.
LL. B. ATKINSON.—1920.
J. S. HIGHFIELD.—1921.
F. GILL, O.B.E.—1922.
A. RUSSELL, M.A., D.Sc., LL.D., F.R.S.—1923.
W. B. WOODHOUSE.—1924.
R. A. CHATTOCK.—1925.
W. H. ECCLES, D.Sc., F.R.S.—1926.
SIR ARCHIBALD PAGE.—1927.
LIEUT.-COL. K. EDGCUMBE, T.D., R.E.T. (Ret.).—1928.

Vice-Presidents.

CAPT. J. M. DONALDSON, M.C.
P. V. HUNTER, C.B.E.
A. H. RAILING, D.ENG.
B. WELBOURN.

Honorary Treasurer.—E. LEETE.

Ordinary Members of Council.

J. R. BEARD, M.Sc.
MAJOR B. BINYON, O.B.E., M.A.
A. R. COOPER.
D. N. DUNLOP, O.B.E.
T. G. N. HALDANE, M.A.
S. HARCOMBE, M.A., B.Sc.
J. M. KENNEDY.
H. MARRYAT.
R. K. MORCOM, C.B.E., M.A.
SIR PHILIP NASH, K.C.M.G., C.B.
C. C. PATERSON, O.B.E.
F. W. PURSE.
E. E. SHARP.
E. H. SHAUGHNESSY, O.B.E.
LT.-COL. W. A. VIGNOLES, D.S.O.
R. S. WHIPPLE.
PROF. E. WILSON.
H. T. YOUNG.

Chairmen and Past-Chairmen of Local Centres.

*T. H. U. ALDRIDGE (*China*).
*W. J. BACHE (*Western*).
*S. E. BRITTON (*Mersey and North Wales*).
K. N. ECKHARD (*Argentina*).
S. B. HASLAM (*Western*).
T. E. HERBERT (*North-Western*).

Inaugural Address by the President (Col. Sir Thomas F. Purves, O.B.E.) 1

Address by Captain C. E. Kennedy-Purvis, R.N., Chairman of the Wireless Section 16

Address by E. W. Hill, Chairman of the Meter and Instrument Section 24

Address by S. B. Haslam, Chairman of the Western Centre 28

Address by G. R. J. Parkinson, Chairman of the South Midland Centre 33

Address by T. J. Monaghan, B.Sc.(Eng.), Chairman of the Irish Centre 36

Address by B. A. Robinson, Chairman of the North-Eastern Centre 41

Address by T. E. Herbert, Chairman of the North-Western Centre 46

Address by Professor E. W. Marchant, D.Sc., Chairman of the Mersey and North Wales (Liverpool) Centre 51

Address by T. Roles, Chairman of the North Midland Centre 56

Address by G. Morgan, Chairman of the Scottish Centre 61

Address by A. D. Phillips, Chairman of the East Midland Sub-Centre 66

Address by R. J. Lawson, Chairman of the Dundee Sub-Centre 69

Address by H. W. Walker, Chairman of the Sheffield Sub-Centre 73

Address by B. Handley, Chairman of the Hampshire Sub-Centre 78

"**The Analysis and Measurement of the Noise emitted by Machinery.**" By B. A. G. Churcher and A. J. King 97

Discussion:

Before the Institution 125
" Western Centre 780
" North-Eastern Centre 782
" North-Western Centre 784

Reviews of Progress:

"Electro-Physics." By D. Owen, B.A., D.Sc. .. 132
"Electrical Plant and Machinery, including Marine Applications." By A. R. Everest 139
"Domestic Applications of Electricity." By C. G. Morley New 147
"Electricity Supply Tariffs and Methods of Charge." By J. W. Beauchamp 152
"The Electrical Equipment of Automobiles." By Professor S. Parker Smith, D.Sc. 156
"Electric Traction." By Lieut.-Col. F. A. Cortez Leigh, T.D., R.E.T. (Ret.), and M. G. Say, Ph.D., M.Sc. 167

THE JOURNAL OF
The Institution of Electrical Engineers
VOL. 68.

INAUGURAL ADDRESS

By Colonel Sir THOMAS F. PURVES, O.B.E., President.

(*Address delivered before* THE INSTITUTION *24th October,* 1929.)

I shall not attempt to express here my sense of the honour which you have conferred upon me in electing me to the position of President of this great Institution. I accept it with warm appreciation as a tribute of friendship and good will to myself, and as a gracious compliment to the branch of public service engineering to which almost the whole of my working life has been devoted.

It is no light matter to step into the shoes of a long line of illustrious predecessors many of whom have written their names enduringly in the history of science and of the material progress of our country.

I cannot hope to add to the lustre of those well-worn shoes, but I draw some comfort from the thought that they must surely by this time have acquired the habit of carrying their wearer automatically in the paths of wisdom and discretion.

THE INSTITUTION.

At any rate I can promise, with assurance, that you will not find me lacking in endeavour, or in loyalty to the causes which the Institution has at heart and which it exists to further.

Its work is on a high level, and we are all entitled to a sense of gratification and pride in its position and its prospects. For the past 8 years it has enjoyed the dignity of a Royal Charter, the grant of which signalized the completion of 50 years of useful life since its foundation in the year 1871. With a membership roll now approaching 14 000 it is the largest professional institution in the Empire, and it is still rapidly advancing, both in numbers and in influence.

It has shown its interest in, and its desire to help, every branch of electrical industry by the recent formation of specialized autonomous sections, which enable their members to obtain all the advantages of direct association and discussion with colleagues having the same immediate interests, while at the same time they enjoy the general professional services, and the powerful backing, of the main Institution. As a result of this policy the Wireless Section and the Meter and Instrument Section have already been launched under conditions which promise permanent satisfaction and success.

At the close of last session the Institution adopted a revised classification of its grades of membership which, I venture to think, has brought its constitution into greater harmony with the conditions of to-day, and has provided a framework on which it will be able to develop itself for many years and to play, I hope, a worthy part in the work which kindred institutions throughout the world are doing to foster the progress of the great profession of engineering, upon which the welfare of nations so greatly depends.

THE ELECTRICAL ENGINEER.

The sphere of the engineer, like that of science, has no definable limits. No matter what the subject of action may be, it is his business to think out the process of "least action" that will secure the desired result. The conservation of energy is always his goal—the expenditure of time, money, and material in the most effective way.

The application of electrical science to industry and to the general service of the human race has become a tremendous undertaking, still young and immature, but growing and branching in unexampled fashion and destined, beyond any question, "to inherit the earth and subdue it," for as long as mankind endures.

Just as the science of electricity is penetrating, and shaping anew, the whole realm of fundamental physics, so will its engineering penetrate the whole field of industry and mould its practices. It has been well said that "the science of to-day is the engineering of to-morrow," and it is our business to make sure that, in the electrical field, engineering shall follow closely and continuously on the heels of science.

EDUCATION.

A great responsibility rests to-day upon the teachers of scientific technology, whose task it is to equip the normal human brain, in a limited term of years, with the elements of knowledge which will best enable the coming generation to take up and carry forward the intellectual side of the world's constructive work. More and more has science become the basis of intellectual advancement, and more and more has it become essential to make a rigorously limited selection of the conceptions of nature's structure and law which can most helpfully be gathered together and impressed upon the mind of youth as a directive guide to the lines of well-balanced progress. No longer is it possible to turn out a finished student into the stream of life. We shall have to be content—and we may well be content—if the graduates of our science and engineering colleges are men with sound fundamental knowledge and with faculties trained to continue the processes of absorption and assimilation; men who know what the tools of science and technology are and how they can be used, and who will be all the better if they have some general idea of the wonderful visions of ultimate things that the most advanced minds of the world are glimpsing to-day from mountain-tops that, to most of us, are still away in the far distance.

The need for specialization is, of course, greater than ever and will go on increasing, but the same may be said of the disadvantage of too early specialization. It is generally the hard and continuous specialist who "delivers the goods," but he can only do that after his college training has been supplemented by intimate contact with the problems of his profession.

The time is rapidly approaching—if, indeed, it has not already arrived—when the teaching of the detailed applications of technology to professional subjects, in full-time educational establishments, will have to be abandoned. The fundamental technique of electrical science and engineering, and its general applications, already furnish more than sufficient material for a full college course. The student will have to wait until he has left college, and has selected and entered his branch of the profession, before he can really begin to learn how his knowledge must be applied in practice. He will learn it then all the better, and all the quicker, because he will be in touch with actual things and actual needs, in association with working experts, and will have the continual stimulus of his natural desire to advance himself in his chosen career.

I should like to appeal to all employers of young electrical engineers to recognize this condition—as, indeed, many already do—and to encourage its application. They should not expect youths straight from college to do useful productive work from the commencement. They should rather be glad to find that a young man knows nothing whatever of how to apply his education to the special problems of the industry, if it means that the precious years of his college courses have been devoted entirely to equipping him with basic knowledge which he would have much less effective opportunity of acquiring in later years, and which has increased his personal potentialities and his aptitude to acquire and use the special knowledge that his experience in the industry will show him to be necessary.

In my own personal sphere I experienced no particular pleasure in finding that a young man who has come to the Post Office from one of our engineering universities has been studying practical telegraphy or telephony or radio communication. On the contrary I am inclined to feel that it will probably take him some time to readjust the focus of what he has learned, and that he might have been better equipped for a life-work in association with those subjects if the time he had already spent in studying them had been devoted to general electrical science and the mathematics of wave propagation. Every branch of the electrical industry should be prepared to train the young men who enter its ranks in the details of their profession, to encourage systematic post-graduate study, and to guide it into the most fruitful channels. It means appreciable immediate sacrifice on the part of employers, but in the ultimate interests of progressive national efficiency it is richly worth while.

We who are getting on in life and have had experience of simpler days, cannot but feel a keen sense of sympathy with the young recruits who are now flocking to join us. The calls made upon them are going to be very severe. The mass of knowledge to be assimilated before one can get reasonably abreast of the leading waves of progress becomes ever greater, and the task of the pioneer who would use them as a point from which to plunge further "into the brown" of the unknown becomes ever harder. I have heard the hope expressed that some day, perhaps in the far-distant future, the balance between Nature and Man will be finally struck. In the meantime, however, there is no escape; we have still to toil on, and we have finished with the casual age.

ELECTRICAL COMMUNICATIONS.

In considering to what particular subject I should direct your attention to-night, I have not been unmindful of the sound old adage that the cobbler is generally well advised to stick to his last, and, on that principle, I propose to say a little on some aspects and activities of the engineering of electrical communications that have contributed to the wonderful expansion of the range of telephony which has taken place since the last reference was made to the subject in an address from this chair on the occasion of Mr. Gill's Inaugural Address in 1922.*

At that time the only places abroad with which a British telephone user could communicate were Paris and Brussels. To-day one can speak from this building, or from any other telephone in this country, to nearly 90 per cent of the telephone stations of the world, and the statement that speech has been interchanged between any two points on the surface of the globe is no longer sensational. The problem of world-wide telephony has now advanced to that of providing public services in such a way that they can be depended upon to operate as and when required by the needs and convenience of the users.

Electrical communications engineering represents the main field of what is known as "light current" engineering. It was the first branch of electrical engineering to be developed into a public service and, as you all know, it was as the Society of Telegraph Engineers that our present Institution was founded in 1871.

---

* *Journal I.E.E.*, 1923, vol. 61, p. 1.

Rapid developments in the generation and utilization of electrical energy on a large scale soon extended the scope of electrical engineering, and the scope of this Institution, far beyond their original narrow boundaries, in ways so striking and so resounding that the mere "milliampere man" began to feel that he had been relegated to quite a humble position among his co-workers in the electrical field. In more recent years, however, he has felt increasingly inclined to lift up his head again. While the power engineer has gone on from strength to strength, piling up volts and amperes on a great scale and doing marvellous things with them, the "light current" engineer has achieved dignity in the opposite direction by converting himself into a micro-volt and a micro-ampere man. I think he may reasonably claim that the intricacy of the problems which confront him and the delicacy of the means and methods which he has devised for dealing with them, will bear comparison with those of any other branch of electrical engineering. The dissemination of power and light, and high-speed loads, by electrical means are great achievements in the service of humanity, but the communications engineer may find inspiration in the reflection that his *métier*—the transmission of thought, intelligence and information—is a no less worthy contribution to the status and to the legitimate pride of the electrical engineer.

Telegraphy and Telephony.—The present position of the Telegraph Service in this country is most interesting and might well have supplied the material for an address, but I shall have to leave it untouched and pass at once to the branch of communications engineering which at the present day provides the most extensive field of operations, namely, the transmission of human speech by the public intercommunicating telephone. It is a branch which involves particularly intimate relations between the supplier and the user of the service. The concern of the public in its efficiency is direct and personal. Any failure to provide without delay for the easy interchange of conversation, on business or pleasure, with any desired correspondent is a flagrant failure of function which may sometimes be excused but can never be concealed. As a result, public telephone services are generally carried on in a stimulating atmosphere of critical vigilance on the part of the users, and this country is assuredly no exception to the rule.

The story of the invention of the telephone, and of the successive stages of its development into an essential tool of business and social life, has often been told and I need not attempt to repeat it. The progress of telephone exchange design is a typical example of the gradual displacement of manual effort by the machine. Multitudes of time-saving inventions have contributed to the progressive restriction and refinement of the part played by the human operator in the working of an exchange.

The Automatic System.—At the present day the installation of full automatic systems, in which even the selection and interconnection of the lines is performed by electromagnetic machines, is being pushed forward with increasing momentum all over the world, and in all kinds of localities from the smallest villages to the largest cities, with improved results in the economy and quality of the service—sometimes, unfortunately, obscured to some extent by the occasional special difficulties of the transition period in large areas where the change-over has to be made in more or less piecemeal fashion. I am pleased to be able to say that the system specially evolved for the service of London, which I had the privilege of describing in advance to this Institution nearly five years ago,* is realizing in practice the hopes that had been founded upon it. Twenty-one large exchanges with an aggregate capacity for about 132 000 lines have already been brought into service in London, in addition to the main junction switching-centre known as the "Mechanical Tandem" Exchange. The provision of 26 further exchanges, with capacity for about 125 000 lines, is now in hand and it is expected that equipment for about 50 000 lines will be added annually to the London automatic system until the conversion of the area, which at present has a total of about 650 000 working telephone stations, is completed and all the manual exchanges are removed. In order to effect plant economies it is proposed to provide auxiliary automatic tandem switching centres, and an automatic switching centre for "Toll" circuits is also contemplated. It is anticipated that in 7 years' time the number of automatic exchanges in the central London business area will have reached 100, leaving only 5 manual exchanges for subsequent conversion. This great grafting and transforming operation—one of the greatest and most complex ever attempted in the electrical field—has necessarily to be carried through while the London telephone organism continues to perform without interruption its function of providing service to all its subscribers by day and by night, and I can say quite definitely that the difficulties and mishaps which have so far been experienced have been considerably less than one was inclined to anticipate at its inception.

The Telephone Exchange System.—It may be mentioned here that in this country as a whole we now have 163 automatic exchanges in operation in urban areas, with an aggregate capacity of about 300 000 lines (say 500 000 stations), and that the planning and construction of 126 further exchanges is at present in hand. The manual system remains in use at the present moment at 487 exchanges having a capacity exceeding 300 lines, and at 3 790 smaller exchanges, serving, in all, about 1½ million stations; and exchange equipment of the automatic type capable of serving about 100 000 lines is being installed annually. It is of interest to record that, at the present rate of development, one new public exchange and about 1 000 new telephones are installed for each working day throughout the year. Rural exchanges have, until quite recently, been entirely manual, but automatic equipment for exchanges serving small communities has now been designed on a basis which promises favourable economic results, and a start has been made in its installation. Up to the present, 60 such village automatic exchanges have been brought into operation, and about 110 more are in hand. The minimum exchange unit provides for 25 lines, and further units can be added up to a maximum of 200 lines. They are accommodated in simple, extensible buildings of the "garage" type and are left unattended. A maintenance man normally visits them about once a week for the purpose of attending to the power plant, renewing the supply of calcium chloride by which the air of the building is maintained in a dry state, and making a general maintenance inspection. One important advantage of these small automatic exchanges is that they provide an all-night service, both locally and to the outer world via junction lines to the nearest "parent" exchange. The expense of providing night attendance at village exchanges of the manual type is invariably out of all proportion to the insignificant number of night calls to be dealt with, and is generally prohibitive.

---

* "The Post Office and Automatic Telephones," *Journal I.E.E.*, 1925, vol. 63, p. 617.

Economics.—The telephone engineer, like his confrères in many other branches of the electrical industry, is called upon to undergo much heart-searching and brain-twisting on the subject of the economics of his constructive work. He has to steer the best possible course between over-provision of plant for the future on the one hand and under-provision on the other, and I think he has some reason for the idea that in the case of telephone plant the course between Scylla and Charybdis is peculiarly narrow and hazardous. The telephone engineer's word "plant" seems indeed a specially appropriate term to apply to the material of a telephone system. It is always growing; always pushing out fresh tentacles in some directions and withdrawing them at other points. For every 100 new stations he joins up he finds, on the average, that about 30 have gone out of service and that partially useless lines are thrown back upon his hands. Conditions affecting development were not particularly troublesome in the early days when exchanges were small and the lines consisted of open wires strung upon poles or overhouse fixtures, which could be supplemented or rearranged at small cost, but modern conditions have sadly reduced the element of flexibility. Exchanges are now immovably established in large special buildings, and the many thousands of lines radiating from them are embedded in cables carried beneath streets and roadways that can only be opened at great expense and inconvenience. The exercise of the utmost possible foresight in determining the primary quantities and lay-out of plant in a telephone area, and all subsequent additions to it, has thus become a *sine qua non*. If the annual increase in the number of telephone users in a section of the area, and the probable trend of the prices of money and materials, are known with approximate accuracy, one can calculate the "economic periods" for which ducts and cables should be provided, that is to say, the quantities which should be laid at one time in order that the "ultimate" development of the area will be provided for by the minimum aggregate expenditure. The ultimate period is taken as 30 years ahead in the case of exchange plant, and 20 years ahead in the case of underground plant, and the calculations are made on the basis of the "present value" of the annual charges for interest, depreciation and maintenance, that would apply to the plant if constructed in quantities designed to meet the requirements of various intermediate periods. Detailed surveys which take all the known social and commercial factors of growing and changing localities into account have therefore to be made and systematically revised from time to time, and on these are based and maintained what are known as the fundamental lay-out plans applying to each area. These show the number, capacity and position of the exchanges needed to serve the area with the minimum mileage of costly copper conductors for subscribers' and junction lines, the local area to be covered by each exchange, and the rearrangement of exchange boundaries consequent upon the opening of each additional exchange, the routes to be taken by duct lines, and the numbers of ducts to be laid, etc.

The highly developed methods pursued in the determination of plant lay-out, in association with power distribution as well as with telephone distribution, were fully stated in the papers read before the Institution last session by Capt. Donaldson and Capt. Hines on the "Anticipation of Demand" and in the interesting general discussions which resulted.* The object aimed at is, of course, the substitution of scientific calculation for intelligent guesswork, and there is no question that the cost of elaborate and careful development study is richly repaid to such telephone administration as the Post Office, which sinks new capital to the amount of about 10 million £ annually in the provision of additional plant to meet its growing requirements, and which would certainly expend very large sums ineffectively if rule-of-thumb methods were depended on.

Telephone Development.—The number of telephones in use in Great Britain is far smaller than it ought to be in a great commercial nation such as this, and, unfortunately, the same remark applies to the amount of use made of the telephones actually in service. Village exchange lines cannot be expected to originate much traffic, but it is very disappointing to find that the total traffic originated at exchanges having 300 lines and upwards only amounts to an average of 5·3 calls per line per day, which is much below the average in many other countries, and it shows no tendency to rise. This cannot be attributed to an unsatisfactory grade of service, because the quality of the service given in this country has for several years been good and the call fee is low. Reluctance to hire a telephone, and to use it after it has been hired, may be a British characteristic, but I am quite sure that it is not an unchangeable characteristic. Much evidently remains to be done to bring home to the minds of our citizens the manifold business and social services which the telephone can render.

The position of this country among telephone users will not be improved merely by pouring more capital into the system. This would be putting the cart before the horse, and the additional interest and other annual charges thrown upon the accounts would soon convert the business into a losing one unless the public market for telephones and telephone service were at the same time correspondingly stimulated. It is only upon the estimated results of new salesmanship expedients that increased expenditure of capital can be judiciously regulated and the additional plant required be made available neither too soon nor too late. The system already carries and maintains the margin of spare plant required to meet continued development at the present rate of about $8\frac{1}{2}$ per cent, cumulatively, per annum. This rate of increase is in itself a healthy one and compares well with the progress which is being made in other countries, but it is not sufficient to enable Great Britain to retrieve its arrears of telephone development in a reasonable time.

---

* *Journal I.E.E.*, 1929, vol. 67, p. 594.

The Post Office has adopted, and is continuing, various expedients to stimulate public interest in the telephone. Intensive personal canvassing, coupled with wide distribution of postcards and pamphlets, has recently been tried in a number of areas. It cannot be said, so far, that these efforts have achieved striking success, but the Post Office takes a hopeful view of the future and has faith that the public will increasingly find the telephone a necessity, both in business and in private life.

The Line.—A feature of communications engineering worthy of remark is the manner in which electrical considerations affecting the transmission line have advanced into prominence. Not very many years ago the indoor apparatus associated with telegraph and telephone systems was regarded as the complex subject, and as the main field for study and invention. Lines were looked upon as simple things, constructed on mechanical principles, and involving chiefly the consideration of strains and stresses, wind pressures, temperature variations of catenaries, and the like. One was expected to provide lines of sound physical design and construction, and then to make the best possible use of them by improving and refining the traffic-handling apparatus. The situation to-day is very different. Notwithstanding the wonderful development and performance of the apparatus of modern communication systems, it is overshadowed by the results of the attack which is now being made by research upon the properties with which the line, the transmitting medium and its adjuncts, may be endowed. All the weapons of the most advanced electrical and mathematical technique are being employed, and it may fairly be said that the contributions which the study of telephony has made to alternating-current transmission theory are of first-class importance to electrical science and practice in general. It is to the study of the ideal wave-transmission line, and to the efforts made to realize its qualities in practice, that we owe nation-wide telephony and the striking progress which has recently been made towards telephony of world-wide range.

Oliver Heaviside.—Our great pioneer in this matter, Oliver Heaviside, was unfortunately not endowed by nature with the faculty of exposition in a diluted form, or perhaps even with much spontaneous inclination to build bridges by which his less accomplished contemporaries could readily follow him to his conclusions and seize upon their practical applications. Recognition of the gifts of his genius to electrical science has come in full measure, largely within his lifetime but rather tragically late. Much of what was truly admiration he regarded as a somewhat unwelcome expression of sympathy. He was elected an Honorary Member of this Institution in 1908 and was the first recipient of its Faraday Medal in 1922, but I have often felt that if the contemporary appreciation of his work had been more adequate and friendly we might have had him amongst us for many years as an active and a jolly working member; if so, our loss has been great.

Loading.—Prof. Pupin has the honour of being the first to show how the harvest of Heaviside's theorems might be reaped by the practical engineer; and the great advance in the telephone art represented by the addition of inductive loading to long-line circuits will always be associated with his name, as well as with the names of Campbell and others who followed him very closely and with great effect.

Pupin showed that an approximation to the balance of line characteristics necessary for the transmission of complex electromagnetic waves without phase distortion ($R/L = G/C$) could be obtained in practice by inserting inductively wound loading coils at intervals which must provide not less than π coils in the shortest wavelength to be transmitted. In practice this is governed by the highest frequency of speech which it is necessary to transmit in order to preserve good tone and articulation, say 2 500 periods per sec. The inductance added by loading increases the electromagnetic inertia of a line and raises its " energy transfer ratio," thereby tending to preserve the amplitude of the transmitted waves and so reduce the attenuation characteristics of the line. In practice, loading-coils are generally inserted at very accurately spaced intervals of about 2 000 yards, and the inductance of the coils is so chosen that the loaded circuits will transmit all frequencies up to about 3 000 per sec. This upper limit is known as the " cut-off point " of the cable and should be about 30 per cent above the highest frequencies needed for good reproduction of speech. In an underground cable with typical loading, say with an inductance of about 155 mH per mile, the propagation speed will be about 16 000 km per sec., giving for the mean speech frequency of about 1 200 cycles a wavelength of about 13 300 metres. Heavier loading reduces the propagation speed and correspondingly reduces the number of coils per wavelength with a given spacing of coils; the cut-off point is correspondingly lowered. On the other hand, lightening the loading increases the propagation speed and raises the cut-off point; a movement in this direction has been occasioned, at some sacrifice in the matter of attenuation, by recent demands for the provision of circuits capable of carrying the higher frequencies—up to 8 000 or more per sec.—required for the effective transmission of music for broadcasting purposes, and of pictures.

The attenuation of open-wire lines can also be reduced by the addition of inductive loading. Since the propagation speed of electromagnetic waves on such lines approximates to the speed of light, the wavelength at any given frequency is correspondingly great, and it suffices to provide loading coils at intervals of 10 to 15 miles. Effective loading, however, calls for a high degree of stability in the leakance of the line, and this factor is one which necessarily varies considerably in the case of a wire carried on open insulators, especially if the climate is damp and variable. For this reason, and also for the reason that the policy of placing long trunk telephone-circuits in underground cables was adopted in this country as soon as loading methods matured, the loading of open-wire routes has never been resorted to here, and it is now being generally abandoned elsewhere.

So far as underground cables are concerned, the introduction of loading immediately increased the practicable range of telephone communication to 3 or 4 times its former limits. Its application is, however, both costly and troublesome. At intervals of about 2 000 yards an underground manhole chamber has to be substituted for a simple straight-through buried joint, in order to accommodate the sealed cast-iron pots in which the loading coils are fitted, and into and out of which the cables have to be led. Many hundreds of loading coils have frequently to be accommodated in a single chamber in which much intricate jointing and plumbing work has to be done under trying conditions.

One would rejoice to find it possible to supersede inductive loading by some less formidable means of reducing the attenuation and the various forms of distortion which appear in unloaded underground cables. Methods by which this may eventually be accomplished, by compensating devices at the ends of the cables, are appearing and coming into use, in the search for further improvements in the transmission line. Phase distortion due to the unequal speed of propagation of the various component frequencies making up the complex speech wave, which would be eliminated by perfect loading, can also be corrected by the introduction, at the terminals of the circuit, of artificial line networks in which inductance and capacity are so disposed that the propagation irregularities natural to the cable are reversed. The lower-frequency components which will arrive too soon, after passing over a cable in which the ratio of inductance to capacity is too small, may thus be retarded and stepped back into their original phase relationship with the higher frequencies which have travelled more slowly along the line.

Similarly the disproportionate attenuation to which the higher frequencies have been subjected in the cable may be corrected by terminal networks, so designed that the lower frequencies are over-attenuated and brought down to approximately their original proportions in the complex wave.

There remains the difficulty of compensating for attenuation as a whole, since the omission of loading coils and the introduction of such devices as those already mentioned—all of which fritter away the energy of the speech wave—will have increased the attenuation factor of the circuit to 8 or 10 times that of the loaded cable line.

It may be thought that the energy loss can readily be made good by the almost unlimited possibilities of amplification now at our disposal; but in practice the amount of amplification that can be applied at any point in a telephone circuit is severely limited by the necessity for avoiding crosstalk between one circuit and another. It is necessary to pack hundreds of pairs of conductors closely together within the lead sheath of a single cable, and the problem of avoiding crosstalk, even at the ordinary energy levels of telephony, by maintaining the greatest possible symmetry of position and uniformity of electrical characteristics of all conductors throughout the length of a cable between repeater stations, is one which calls for the greatest care and accuracy in manufacture. It has been necessary also to devise an elaborate system of testing the resistances and various cross-capacities of all the pairs in each cable length after the cable is drawn into ducts, in order that pairs having high and low characteristics in each length, and successive groups of lengths, may be selected and matched together in such a way that variations in the manufacturing lengths may be made to cancel each other out as far as possible in the completed cable.

All that can be done at the successive amplifying points in a long line is therefore to restore the energy to a level not much exceeding the energy output of the subscriber's telephone.

Any two adjacent circuits near the end of a telephone cable between repeater stations are liable to be carrying, respectively, the comparatively high energy of speech from the near end amplifier and the much attenuated energy of speech from the far end. In practice, a ratio between the sent and received power of about 40 to 1 is maintained on 2-wire circuits. If this ratio were much exceeded, either by adopting a higher level of output or by allowing the received energy to sink to a much lower level before amplification, the crosstalk from the near end would cause proportionately greater interference with the intelligibility of the speech received from the far end. Each repeater station along the line would contribute its quota of additional crosstalk, to be amplified by successive repeaters, and chaos would result. The present system by which amplifying devices are used merely to restore the normal minimum energy of received speech to the normal level of transmitted speech, by an amplification averaging about 40 to 1 at each point, enables repeater stations to be installed 50 miles or more apart. If unloaded cables were used, the stations would have to be so close together that their cost would far exceed the cost of loading the cables. The answer to the frequent question whether amplifying and distortion-correcting devices have sounded the death-knell of inductive loading is therefore decidedly in the negative, and it is clear that the art of cable manufacture will need to achieve another order of freedom from crosstalk, before an answer in the opposite sense can be given.

This is not intended to imply that telephone cable design and manufacture are in any sense open to the charge of being non-progressive. On the contrary, steady improvement is being made in the mechanical symmetry and electrical uniformity of the circuits and in the means of providing circuits for special purposes, as well as in the economics of production.

The Telephone Repeater.—Apart from conductors and cables, as such, the study of the transmission line must be credited with a wonderful range of inventions designed solely from the standpoint of improving it as a transducer, and included strictly within the limits of the line quadripole.

Facile princeps among these must be placed the telephone repeater, developed on the basis of De Forest's conversion of the Fleming valve into a triode amplifier and since improved in all directions by many inventors and engineers. For many years an effective repeater which would regenerate speech currents, and pass them forward automatically in the manner of our well-known telegraph repeaters, had been longed for by telephone men who were straining to extend the range of communication. Never did the seed of an invention fall upon soil better prepared to receive it and to promote its rapid growth, and never was a long-standing fundamental problem solved in a more complete and satisfying manner. It harnessed for the first time the simplest known element of nature, the flying electron, not, indeed, an agent independent of time and inertia, but one making a demand upon these conditions that, from our gross material standpoint, is almost infinitely small. Its practical applications in telephony were taken up at once with unbounded enthusiasm on all hands.

England was the only nation in which an appreciable proportion of trunk telephone circuits had been laid in underground cables before the advent of the valve, and the range of such communication was limited to a little over 200 miles. To reach the Liverpool and Manchester areas from London, loaded cables carrying wires having a weight of 300 lb. of copper to the mile were in use. In a very short time the lay-out of the trunk system was entirely replanned on the basis of using light-gauge cable conductors—20 lb. and 40 lb. to the mile—working through repeater stations, and an era of rapid trunk cable construction set in, which has since had its counterpart in all the major nations.

Each repeater on an ordinary 2-wire circuit is arranged for transmission in both directions, on the general principle of the differential telegraph line duplex, and this has necessitated the development of artificial line networks which simulate the characteristics of the actual line so closely that they are capable of balancing it throughout the whole effective range of speech frequencies.

Four-Wire Circuits.—The need for such balances at the line repeaters, and for other refinements which are difficult to apply on very long circuits, can be avoided by the use of 4 wires for each circuit, one pair carrying speech in one direction and the other carrying it in the reverse direction. This 4-wire system is now in general use on the longest classes of circuit throughout the world. It permits the use of higher degrees of amplification, since crosstalk can be minimized by placing the outgoing transmitting pairs and the incoming receiving pairs of the cable in two separate groups, and by protecting the receiving group by electromagnetic and electrostatic shielding against interference from the comparatively strong currents of the transmitting group. No doubt the amplification used, and consequently the distances between repeater stations, could be further increased by the more effective shielding which would result from placing the transmitting and receiving sides of the circuits in entirely separate cables. This would, however, involve extensive rearrangement and reconstruction of existing systems, and, moreover, I think it is reasonable to hope that further improvements in cable construction, and in the 2-wire system for circuits of equally light gauge, will eventually cause the 4-wire circuit to disappear or become a rarity. It is essentially a double-line circuit, only one half of which is in effective use at one time, so that its doubled weight of copper contributes nothing to the transmission efficiency of the line.

Electrical Echoes.—A phenomenon which gave a good deal of trouble in connection with the first attempts to provide very long telephone cable circuits was the occurrence of electrical echoes. If the time of transit of the speech waves from the transmitting to the receiving end and back again by reflection exceeds about $\frac{1}{16}$ sec., the effect in the ear of the speaker is very confusing and may be rather disastrous to the intelligibility of the conversation. The effect is, of course, equally marked in the case of 4-wire circuits, although on such circuits the possibilities of lighter loading, with consequent increase in the speed of wave propagation, extend the distance that can be covered before the return of the reflected waves is retarded beyond the permissible time. It was at one time thought that such echoes would set a practical limit of about 1 000 miles to the length of cable circuit that could be used for telephony. The difficulty was overcome by the invention of voice-operated echo suppressors applicable to the 4-wire circuit. These devices utilize a small derived portion of the speech current, passing on the active half of the double line, to energize delicate devices which temporarily block the inactive half against the return of reflected current. In the suppressors first devised by the Post Office the blockage was effected by over-priming the grids of the repeater valves in the inactive line to an extent which put them temporarily out of action. In another type of suppressor, sensitive relays actuated by amplified speech currents are employed to produce an actual disconnection, or a short-circuit, of the inactive line. Both types are in practical use, with satisfactory results.

The Post Office type of echo suppressor has been successfully applied to experimental 2-wire circuits, but other considerations at present limit such circuits to lengths on which the echo effect is not noticeable.

Reflections are, of course, produced only at points where changes in the electrical characteristics of the circuit are introduced, and the setting-up of echoes can be minimized by preserving the utmost possible uniformity throughout the length of the line. Echoes from terminal transformers and from other apparatus at the end of the line can similarly be reduced by reproducing as closely as possible, in the apparatus itself, the characteristic impedance of the line, so that the wave energy will be absorbed with minimum reflection. It is not possible in practice, however, to match the impedances of all parts of the system so perfectly as to secure the complete suppression of distortion due to reflection.

Repeater Refinements.—The use of the repeater on long circuits has now become universal throughout the telephone world. Among many refinements which have been developed in association with their use mention may be made of devices for ensuring the constant energy-level of the amplified speech, independently of the level of speech incoming to the amplifier.

In one such device the amplification is regulated by varying the impedance of a 3-electrode valve, the requisite smoothness of control being obtained from a condenser and resistance combination.

Thus low levels due to weak voices, or to faulty lines, may automatically be made good at the amplifiers, and unduly high levels may be toned down. These devices have reached their highest development in the terminal apparatus by which the transatlantic radio circuits are connected to the ordinary telephone circuits of England

and America, but they are also being applied in a simpler form to inland trunk circuits.

Another device which it has been found desirable to introduce provides for automatically regulating the amplification to compensate for the effects of changes of temperature. If the temperature of a line containing a chain of repeaters rises, the attenuation of each section of the line will be increased and the consequent percentage losses will be multiplied together by the repeaters, with fatal results on the volume of speech received at the ends of the line. To operate the correcting device a wire on the same poles as the working circuit, or in the same cable, is used as a "pilot wire." The variation with temperature in the resistance of the pilot wire is used to operate a regulator which controls the amplification factor of the repeaters. Long circuits of open wire, or in aerial cable, are particularly exposed to sudden changes of temperature. In Great Britain, where practically all the circuits equipped with repeaters are in underground cables and considerable variations in the temperature of the conductors occur only very slowly, it is not necessary to use such automatic devices for maintaining correct amplification.

Mechanical and Acoustic Analogies.—It is interesting to note that the study of the theory of electrical wave transmission, arising, to a great extent, out of the work of Heaviside, has done more than replace the former imperfect theories and place new mathematical tools in the hands of the telephone engineer and of the power engineer dealing with the propagation of high-voltage currents. The conception of electrical impedance—the vector sum of resistance and reactance components—includes factors which have wider relationships in nature, and which apply also to the transduction coefficients of more grossly material agencies, which, from this standpoint, may be regarded as the mechanical analogues of amperes and volts. A good deal of the knowledge acquired in the study of the problems of electrical networks has been found to be applicable, in analogous form, to mechanical and acoustic problems, and many of these are now being solved by methods and reasoning similar to those used in designing electrical circuits and by the use of the appropriate electrical formulæ. An interesting case in point is the work of the Bell Telephone Laboratories in the development of the modern high-quality gramophone. The problem in gramophone-recording was to intercept air vibrations and translate them into vibrations of the recording stylus; and similarly to translate the vibrations of the needle-point into air vibrations which should be a faithful reproduction of the original sounds. In the latter process we have a transmission system, containing the mechanical equivalents of capacitance, inductance and resistance, in much the same arrangement as in the loaded telephone line. To name a few of these elements, there is first the shunt "capacitance" of the needle-point; the series "reactance" of the mass of the needle-arm, and the shunt "capacitance" of its flexibility, associated with homologous properties of the spider and the diaphragm. Taking into account the properties of available materials and the requirements to be met, it was possible to design a reproducing system with much improved tone-range and uniformity of response.

Carrying the application of electrical theory into the field of air vibrations, it has been found possible to design acoustic filters which will suppress undesired frequencies while allowing others to pass. A promising field for these filters is in the ventilating ducts for sound-proof rooms.

The C.C.I.—I have already mentioned the presidential address delivered from this chair 7 years ago, in which Mr. Gill called attention to the progress made in long-distance telephony in the United States and described the possibilities and the results of developing international communications on this side of the Atlantic to a corresponding degree. His remarks attracted widespread attention, and acted with a kind of trigger effect upon the telephone engineers and administrations of war-riven Europe, releasing accumulated desires and plans for the resumption of mutually helpful relationships, and for the furtherance of business intercourse and social understanding by providing a higher order of facility for the direct interchange among nations of the spoken word. At that time there was very little international telephony. As I have already mentioned, Great Britain communicated only with Paris and Brussels and, through those cities, with a few of the other principal towns of Northern France and Belgium. Elsewhere in Europe telephonic relations were confined to communication between the chief towns of adjacent countries, by means of overhead lines.

Within a few months of Mr. Gill's address, and avowedly as a result of it, France took the first step by inviting representatives of the telephone administrations of Western Europe to a conference in Paris in the summer of 1923. At that meeting it was at once apparent that there existed a keen desire for concerted action. The technical and administrative position was surveyed and methods of co-operation were formulated. Programmes of works were drawn up, mainly in the shape of proposals for the building of overhead circuits to meet more or less obvious immediate needs, and the requirements of the future were roughly estimated. The engineering and operating practices of different nations were compared and machinery was set up for the study of a large number of important points which would have to be settled before the construction of an adequate and properly co-ordinated international telephone network could be proceeded with. Rules and specifications of a general character were drawn up in tentative form, defining the essential characteristics of cables, repeaters, switchboards, transmission apparatus, signalling methods, and testing and maintenance procedure which would have to be adhered to in the international service.

It may be remarked here that the need for plant and operating uniformity at all points in an international telephone system is a special feature of telephony which distinguishes it from other systems of communication. Letters or telegrams may be received at intermediate points and passed forward by any available method or route, but the operation of telephony demands that all parts of the system shall work uniformly together.

By the following year, 1924, it had been possible to secure the co-operation of all the belligerent nations of the Great War, and in April of that year a further meeting was held in Paris, attended by representatives of 19 countries—Austria, Belgium, Czecho-Slovakia, Denmark, Finland, France, Germany, Great Britain, Holland, Hungary, Italy, Lettonia, Luxembourg, Norway, Poland, Spain, Sweden, Switzerland and Yugo-Slavia. This Conference definitely constituted itself as a standing advisory Committee on international telephony ("Comité Consultatif International," referred to in brief as the "C.C.I.").

After some rather embarrassing flirtation with the League of Nations, in which I am bound to say that the Committee adopted a somewhat coy and reluctant attitude, it was, at the end of the year 1925, definitely adopted by its natural protector the International Telegraph Union, and it now forms a permanent part of the structure of that world-wide international association. Subsequent adhesions to the C.C.I. include the State Administrations of Albania, Dantzig, Esthonia, Lithuania, Mozambique, Portugal, Roumania, Russia and Persia; and by a recent decision regarding the definition of membership the Committee is now open to the adhesion of privately-owned telephone operating administrations. Under this provision Cuba and Mexico are now represented in its membership. The American Telephone and Telegraph Co., which has from the beginning helped the Committee in all possible ways most generously and effectively, has also been enabled by the new conditions of membership to join the Committee and thus add its great influence and prestige to its work in the cause of world telephony. We should warmly welcome also the appearance of Japan and of the British Dominions at the board. The surface of our globe now sets no limits to the range of the telephone, and the degree of progress made since the date of Mr. Gill's call to arms is, I think, something to warm his heart.

The International Advisory Committee carries on the details of its work by means of small commissions of assessors—"Commissions de Rapporteurs"—each consisting of a few experts selected to study and report upon a particular subject or problem assigned to them. It is one of the duties of these commissions to maintain full touch with the experts in private manufacturing industry and to see that their views are adequately represented in all discussions on the subject of technical plant. The main committee holds a plenary session annually, generally in Paris where its secretariat is located, but occasionally elsewhere. At these conferences the reports of the assessors are reviewed and recommendations are prepared and issued to all the constituent administrations. The committee does not issue mandatory regulations, nor has it any power to do so. Its function is confined to the giving of advice, which each administration is free to accept or reject. The system works smoothly and well. Recommendations passed at plenary conferences are justly regarded as the results of careful and disinterested study and are, almost without exception, accepted and given effect to so far as the ways and means of each administration will permit. I have had the privilege of attending, on behalf of this country, the plenary conferences of the committee from its beginnings, and I gladly testify to the fine spirit of co-operation and friendly concession which has been their characteristic throughout.

It will be recollected that Mr. Gill strongly favoured the entrusting of international telephony in Europe to a single company, or, in default of that, to a single organization set up by the existing administrations to carry on the business as a separate entity. No doubt either of these plans would, from the standpoint of efficient working, have been superior to the present system since, even with the best will in the world, co-operation is but a poor substitute for unified control. The opportunity of skimming the cream of Europe's telephone service would have appealed strongly to anyone to whom it might have been entrusted, but there never was the slightest chance that the existing telephone administrations would give it away. As a rule they look to the trunk system between busy centres, both national and international, to earn a little honest profit which helps to bear the burden of many unremunerative fringes of service which a national telephone administration is compelled to carry on in the interests of the public. It is also true that the political and economic situation in Europe does not readily lend itself to the setting up of independent international bodies whose activities would limit the sovereignity of its national services. The co-ordination of the international telephone system by a committee on which all the administrations are represented, on a basis of equality, was Mr. Gill's third alternative, and no doubt the one he loved the least, but it has proved to be the only one realizable in practice, and it cannot be said to have been barren of results.

The Transmission Unit.—There is, however, one much-debated matter in which the committee has entirely failed to reach a common agreement, i.e. the setting up of a unit in which to measure and express the attenuation accompanying the passage of an electromagnetic wave through any kind of transducer—open wires, cables, transformers, artificial networks, or any kind of apparatus combination. In its practical operation, the unit has merely to express numerically the ratio between the measured or calculated values of power, voltage or current at the extremities of the part considered, and when the question of approving a unit for world-wide use was first raised by Great Britain, one did not anticipate any appreciable difficulty in arriving at accord on the subject. In order to avoid the need for multiplying or dividing a series of ratios to arrive at additive or differential values, it is convenient that the unit should express, not the ratio itself, but its logarithm. One can then simply add together the units representing the attenuation of each element of a combination in order to obtain the attenuation of the whole in the same units. This was common ground, but the rock on which we split was that, in the view of America, Great Britain, and two or three of the Continental nations, "common" logarithms to the base 10 should be used and the measure should be that of *power*, while a majority in Europe desired to continue the use of "natural" logarithms, to the base e, and to apply the unit to the measurement of *current* or *voltage*. The latter attitude is supported by the convenient use of natural logarithms in the mathematical development of line-transmission theory, and the universally established Continental practice of expressing attenuation in terms of decrement of current, or, when phase differences are considered, in terms of the square root of the volt-amperes. Its advocates maintain that there is no need to frame a transmission unit on any other basis. The other side contends that the measurement of attenuation is more properly based directly upon power loss, which applies to the acoustic as well as to the electrical aspect of telephony, and that the use of common logarithms on the decimal base to express the unit has all the advantages which have led to their general adoption in other numerical calculations.

This is not the time or place to add to the discussion, which, in my opinion, has made mountains out of mole-hills and has wandered much too far into purely theoretical considerations. It will suffice to say that continental Europe and America each continue to use the system with which they have identified themselves. Great Britain, which has intimate telephone relations with both parties and which has from the first expressed its readiness, in the cause of uniformity, to adopt either unit, is thus compelled to use both systems in its international relations, but has joined America in the adoption of the decimal system for its internal purposes.

It has been agreed that the Continental unit shall be known as the "napier" (written "néper" on the Continent), as a compliment to the inventor of natural logarithms. One unit represents a ratio of current or voltage values $= e/1$; 2 units $= e^2/1$ and so on.

The basic unit of the decimal system has been called the "bel," in which abbreviated form it enshrines the name of Dr. Graham Bell and also, somewhat fantastically, recognizes the oft-recurring symbols e and βl, of transmission theory. One unit represents the power ration of 10 to 1; 2 units 100 to 1, etc.

The number of népers expressing the decrement of current or voltage, and the number of bels expressing the decrement of real or apparent power in any circuit, differ from each other by only about 15 per cent. Both units are so large that in everyday work it would be necessary to use fractional values.

Practical units of one-tenth the logarithm have, therefore, been introduced with the names "deci-néper" (e to the power of 0·1) and "decibel" (10 to the power of 0·1). These units have the advantage of avoiding to a great extent the writing of fractional values, since one unit represents just about the minimum change in attenuation that is recognizable by the human ear in a telephone receiver. In the literature of the decimal system the decibel (db) is now in general use, but I have so far seen no indication that the deci-néper is likely to displace the fractionally expressed néper on the Continent.

An unfortunate effect of the failure to agree is that much expensive measuring apparatus calibrated in accordance with each system continues to be constructed year by year. The material cost of unification, which would have been small when the first attempt to achieve it was made, thus increases as time goes on.

The Standard Reference System.—One of the tasks of the International Committee has been to define and construct a universal physical standard of reference in order to ensure the strictly equivalent calibration of all apparatus used for measuring the transmission efficiency of telephone transmitters, receivers, lines, and transmission plant in general. No universal standard, either relative or absolute, had previously existed.

The form of apparatus eventually chosen for the purpose was developed by the American Telephone and Telegraph Co., and the Committee has also to thank that company for having presented it with a complete installation of the apparatus, which is an exact duplicate of the reference standard set up in the company's laboratories in New York. The European installation is set up in Paris and is owned and operated by the C.C.I. It represents an absolute acousto-electric standard and is defined in terms of C.G.S. units, so that it could be reconstructed even if its physical representation were destroyed. The process of putting this basic reference standard in the hands of all telephone administrations and manufacturers, by means of working standards which will be periodically calibrated in the reference laboratory, is now being actively pushed forward, and it is anticipated that a higher standard of general efficiency will result from the elimination of the discrepancies which have hitherto existed in the standards of the various authorities.

Radio.—A vast new field was opened up by the production of Hertzian waves and their utilization for communication purposes. The literature of the subject is well represented in the *Journal* of our Institution. Radio telegraphy, in which the alternative emission or cessation of simple waves, or their alternative tuning and detuning, sufficed for signalling purposes, was speedily followed by radio telephony, in which the simple fundamental wave is used merely as a medium, or carrier, on which the complex speech wave can be impressed by modulation and subsequently separated out again and restored to its original character by demodulating processes at the receiving end.

The most impressive special services performed by radio to-day are those of the telegraph with ships at sea, which in the case of the Post Office station at Rugby is capable of reaching any properly equipped ship in any of the waters of the globe; the wonderful services of broadcasting throughout the world; and the transatlantic circuits between London and New York, by means of which all the millions of telephone users in America and in Europe are now linked together and provided with the means of verbal communication one with another at any time desired.

The classic occasion last year on which this Institution and its sister Institution in the United States held a joint meeting, at a time arranged and announced long in advance, will be fresh in the minds of our members; and its significance will be best appreciated by those of us who have had some experience of the chasing of far-distant radio stations, and of the exasperating way in which short and spasmodic periods of success are followed by relapse into the blank of failure.

The stability of the service between Europe and America depends primarily upon the "long wave" channel originally installed. This channel operates on a carrier wave of 5 000 metres and radiates energy averaging about 60 kW. There are also two short-wave channels each using waves of the order of 16, 24, and 30 metres and radiating about 5 kW; this radiated power will shortly be increased to about 10 kW. The provision of a further short-wave channel is now in hand, and endeavours are being made to obtain the availability of a frequency band in the crowded ether which will enable another long-wave channel to be established.

These radiated energies, both long-wave and short-wave, are very much more effective than similar amounts of energy used in ordinary broadcast practice.

In the case of the long wave it is possible to eliminate and suppress the bulk of the energy-consuming components of an ordinary radio-telephone wave, as used by all other radio-telephone stations, and to transmit only that part of the frequency spectrum essential to the reproduction of articulate speech. When a carrier wave is modulated by speech into a telephone transmitter each frequency component of the speech wave appears as two separate frequencies, one equal to the sum of the carrier and component frequencies, and the other equal to their difference. The complex speech wave thus sets up two frequency side-bands extending above and below the frequency of the carrier. Before the energy is amplified for radio transmission the carrier frequency itself, which is the main power element, is filtered out. One of the side-bands, and the non-essential portions of the other, are also filtered out. There remains for amplification and transmission only that portion of one side-band which, after treatment at the receiving end, will reproduce speech frequencies between 300 and 2 500 periods per sec. In this way the effectiveness of each kilowatt of radiated energy is increased about 6 times. By the use of highly directional receiving antennæ a great increase in the ratio of signal strength to noise admittance is secured, and an effective improvement factor of about 100 is introduced. A further improvement in efficiency is obtained by locating the receiving stations in regions which have been found to be comparatively free from "atmospherics." With this object the American receiving station has been established at Houlton (Maine), 600 miles from New York, and the British Station has been located at Cupar, Scotland, 450 miles from London. It has been calculated that a further improvement factor of about 50 was obtained by shifting the receiving station from New York to Houlton. In the case of the short-wave channels the carrier waves and both side-bands are at present radiated, but these channels have the advantage of directional transmission, as well as reception. It results in the energy used in all the London—New York circuits being many thousands of times more effective than equivalent energy radiated, on ordinary broadcasting principles, from one of those places for reception at the other.

Since the establishment of the London—New York system more than 25 000 successful conversations have been effected. The present traffic from all sources at each side averages about 45 calls per day, and the average duration of calls is about 6 minutes. The division of the traffic averages at this side:—

95 per cent from the United States
4 per cent from Canada
and 1 per cent from Cuba and Mexico.

At the other side they get:—

53 per cent from Great Britain
34 per cent from France
7½ per cent from Germany
and 5½ per cent from other European countries.

The behaviour of the circuits is continuously supervised and calls are classified as follows:—

Good—	When conditions are normal and conversation is easy.
Fair—	When additional time has to be allowed as compensation for interruptions.
Poor—	When conversation is difficult and double time, or more, has to be allowed as compensation.
Ineffective—	When the attempt to communicate intelligibly has to be abandoned.

As might be expected, conversations between America and Continental nations, which would be comparatively easy between correspondents speaking the same language, are occasionally rendered bad, or hopeless, by language difficulties.

The classification of calls for the past three months between Great Britain and the Eastern States of America was 85 per cent good and 15 per cent fair. To the Western States and Canada the proportions were 76 per cent good and 24 per cent fair. The whole of the traffic handled was classified as 80 per cent good, 19·7 per cent fair, 0·2 per cent poor and 0·1 per cent ineffective.

The charts on the wall (reproduced on page 12) show graphically the periods of good and bad service on long-wave and short-wave channels for a month, in winter and in summer. The black vertical lines denote good service at the hours of the day during which the channels were worked, marked as ordinates on the left, and the interruptions to these lines show interruptions of service. It will be seen that during the month of December the long-wave channel was 100 per cent commercial during most of the days, and that short uncommercial periods occurred on a few days.

The short-wave channel was subject to more frequent stoppages, but the combination of the two services ensured a practically 100 per cent service throughout the month.

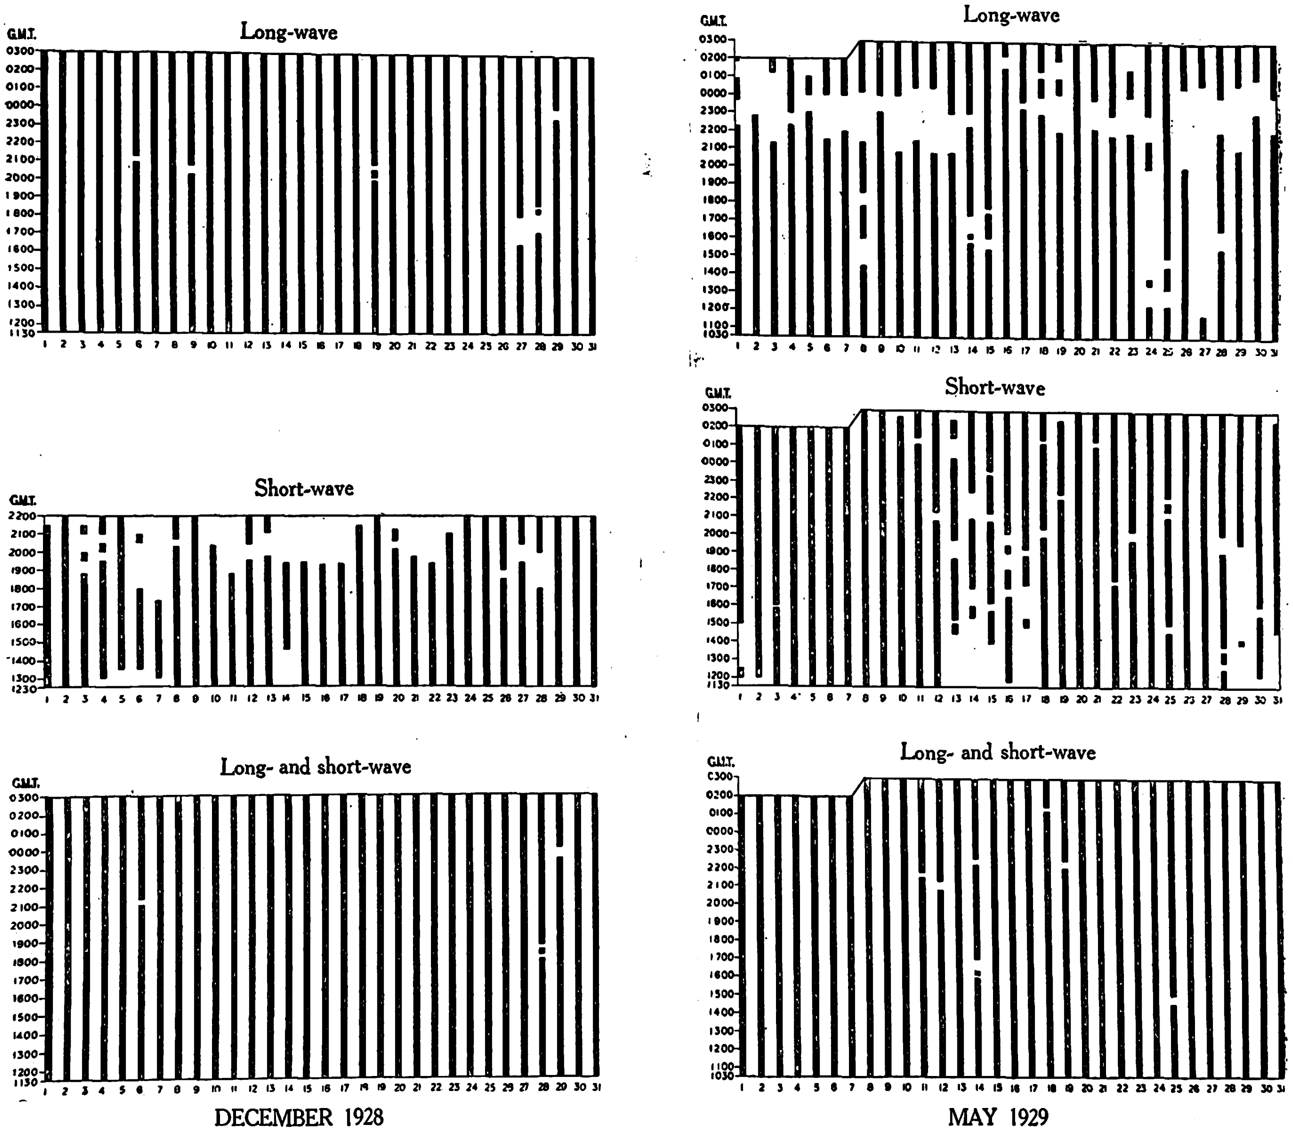
During the month of May, chosen because it shows somewhat abnormal interruption on the long-wave channel, this channel was subject to uncommercial periods, especially around the sunset period over the Atlantic, but it will be seen that the short-wave channel functioned well over that period as a complementary channel, and that the result of the combination of the two channels again ensured practically 100 per cent continuity of service at all times of the day during this month.

I should mention that the short-wave results shown are those of the first and least efficient channel installed. The second short-wave channel, brought into service in June last, has ensured full continuity of service at all times. When the third short-wave channel is provided at the end of this year there will be four channels available to take care of peak loads.

Although the general quality of the service may be regarded as satisfactory at the present early stage of transatlantic telephony, I think it may, with safety, be said that the possibilities of further developments in the art of linking radio circuits with telephone lines are such that the commercial data so far provided by the Anglo-

American service is very far from representing the ultimate grade of service which will be obtained from such circuits.

"*Privacy*" *in Radio Telephony.*—Since radio is necessarily to some extent a broadcast method of transmission, the transatlantic telephone has been subject to the disadvantage that the conversations passing over its radio link may be picked up and understood by other parties. Although such a possibility exists, however, it is not at all an easy matter for an unauthorized listener to "tap" its communications, and there is no reason to think that such tapping actually takes place.



Charts showing interruptions of New York—London telephone service in the months of December 1928 and May 1929.

The voice-actuated control devices employed on both the long-wave and short-wave channels now in operation have incidentally the effect that a receiving set on one side of the ocean can hear the messages transmitted from the other side only by listening directly to the radio station in the distant country. This, in general could only be done reliably by employing receiving systems approaching in cost and elaboration those employed in the commercial circuits. For practically all the time with the long-wave circuits and for the greater part of the time with the short-wave circuits an outside listener would therefore have to be contented with hearing only one side of the conversation, a condition which goes far towards removing any interest which he might have in overhearing a conversation.

The long-wave channels present special difficulties to would-be listeners because the frequencies transmitted represent only a portion of one of the side-bands, the carrier itself and all other modulation frequencies being suppressed. At the receiving point very accurate replacement of the carrier frequency and delicate filtering operations are necessary in order to reproduce the original speech.

Methods of imparting secrecy, or at least a high practical degree of privacy, to the systems have, however, been devised and much close attention is being given to their development.

In the existing short-wave channels, where both side-bands and the carrier are transmitted, directional propagation imparts a certain measure of privacy. It is possible also to vary the carrier frequency or to change the relations between the two side-bands, or between them and the carrier, in such a predetermined manner as to make it very difficult for the speech to be picked up and understood. Such methods have been tried out experimentally with promising results, and were for a time in actual commercial use in connection with a temporary radio-telephone service connecting the Island of Catalina on the Pacific coast of the United States with the Bell telephone system.

In the case of the long-wave channels it is possible to separate the spectrum of the transmitted partial side-band into strips and to invert and mix them in many arbitrary and successive combinations by complex heterodyning processes, which have to be fully known and carefully reversed at the receiving end. It is hoped that it will in this way prove practicable to transform the radio waves into an unintelligible jumble and to restore them, after reception, to their original shape for transmission over the land lines.

I do not wish to suggest that secrecy in radio telephony is yet in sight, in the sense that a competent outsider who is prepared to spend the necessary time and money in making arrangements to overhear conversations would never be successful, but I have little doubt that the system will ere long be equipped in such a way that a sustained and very elaborate attempt would be necessary in order to do so.

Contribution of Line Telephony to Transatlantic Radio Communication.—It is of interest to note that many of the special features of the transatlantic radio system, on which it depends for its commercial success, are devices intimately connected with, and in some cases borrowed from, the developments of line telephony.

Thus the single side-band system of transmission, used on the long-wave circuit, was developed originally in connection with the high-frequency multiplex system of telephony over land wires. It is no exaggeration to say that without this system commercial long-wave telephony across the Atlantic would be an impossibility.

The radio circuit is set up on the principle of a 4-wire telephone circuit connectable at both ends to 2-wire or 4-wire extensions, and it thus conforms to all the conditions associated with the linkage of land networks.

The voice-operated switching devices used on the radio circuit are fundamentally similar to the echo-suppressors evolved for use on long 4-wire land circuits, but much special development has been necessary to meet the far greater crosstalk and interference difficulties of the etheric path.

While it can be said that the radio-telephone system owes much to telephone development it, in its turn, is benefiting the development of line transmission because of its insistence upon the highest grade of design and construction in the land networks to which it has to be extended.

Transatlantic Telephone Cable.—Notwithstanding the high degree of stability which has been attained on the existing group of transatlantic radio-telephone channels, the system would gain greatly by the addition of a submarine cable channel to the facilities available. It has been felt that while such a cable would be so costly that, taken by itself, its provision would be financially impracticable, the expense could be justified in the case of a cable which formed part of a larger system, to which it would impart the valuable element of assured continuity of service and unchallengeable secrecy, as well as adding to the total traffic-carrying capacity of the system. The research laboratories of the American Telephone and Telegraph Co. had succeeded in producing remarkable improvements in the construction of ocean *telegraph* cables by the development of new metallic alloys for inductive loading, known as "permalloys." Its engineers were thereby encouraged to tackle the problem of the ocean telephone cable, with the result that last year the company announced that the Bell Telephone Laboratories had evolved a method of deep-sea telephone-cable construction which would be suitable for transatlantic operation. Work is now going forward actively on the development of a cable of this type for connection between London and New York, and it is possible that this circuit will be available for service as early as 1932. The new cable will yield only one additional telephone channel, but it will be a circuit of maximum reliability, free from the variations characteristic of radio circuits. It is probable that a superposed telegraph channel will also be obtainable.

The route of the cable is not yet settled in detail, but it is probable that the main transatlantic link will extend directly from Newfoundland to Ireland, a cable length of approximately 1 800 nautical miles. From Ireland the circuit will probably be carried through submarine cable to Scotland and thence by land cable to London, where it will terminate. It is expected that from Newfoundland the circuit will be carried through several sections of submarine cable to Nova Scotia and thence by land circuits through Nova Scotia, New Brunswick and the New England States to New York City, which will be the other terminal.

The new cable will be of the continuously loaded type. For the loading material it is intended to use one of a new series of alloys which are designated as "perminvars." These are composed of nickel, cobalt and iron, to which may be added small amounts of non-magnetic metals such as molybdenum. The so-called "perminvars" are characterized by high resistivity and by a wonderfully constant permeability over a wide range of magnetizing force.

The conductor will be insulated with a new dielectric material known as "paragutta." Submarine cables in the past have been insulated with gutta-percha or closely related materials, and in a few cases with rubber compounds. Paragutta makes use of similar raw materials and its mechanical properties are similar to those of gutta-percha, but the combination and treatment of its constituents endow it with superior electrical properties, approximately equal to those of tightly packed dry paper.

The attenuation represented by the main cable link between Newfoundland and Ireland will be immensely greater than that of any other telephone circuit which has yet been planned. It will, indeed, be such that the ratio of input to output power between the repeaters at its two ends will be about 10^{15}, or the equivalent of 150 decibels, for the high frequencies of the voice range; that is to say, the received power will be one thousand-million-millionth of the transmitted power. This decrement is, of course, far greater than that at which ocean telegraph cables are operated, and is indeed of about the same order as that experienced on the transatlantic radio circuits themselves.

The possibility of operating successfully through a line attenuation of this phenomenal magnitude depends upon two special features of the cable: first, the characteristics of perminvar, which permit the use of a level of transmitted power much in excess of that which can be used in an ordinary telephone cable; and second, the careful shielding of the cable ends, for many miles from each shore, against the possibility of even the slightest interference from other electrical circuits. The received power will be so extremely low that even the minute currents, or surges, caused by thermal agitation of the atoms of the conductor become an appreciable source of disturbance. It is anticipated, however, that the received speech currents will be successfully amplified and passed forward in good shape to the next section of the line.

The end repeaters will be single-way amplifiers and, in order to make 2-way conversation possible, voice-operated switching mechanisms will be employed to control the direction of transmission. Thus the two persons engaged in conversation will, by the mere act of speaking, alternately switch the transmitting amplifiers into action at each end as required and conversation will proceed in a perfectly natural manner.

Imperial Telephony.—The great success which has been achieved in the transatlantic radio-telephone service has led to investigations into the possibilities of opening telephone services with other distant systems, particularly with those of the British Dominions.

The first of these undertakings to take practical shape is communication with Australia. By the use of short waves an Anglo-Australian service of an experimental character has for some time been maintained via the Post Office radio stations at Rugby and Baldock, working to the corresponding transmitting and receiving stations near Sydney. It is hoped that a regular commercial service will be inaugurated very soon, and it is anticipated that this will shortly be followed by services to South Africa, India, New Zealand, etc. There is no doubt that direct exchange communication will also be established ere long with ships at sea and with other remote countries where radio telephony installations are being operated or installed.

Restricted Ultimate Field of Radio.—The demand for radio channels is continuously increasing, but the number of frequency bands available in the ether is strictly limited. It is probable that progressive increase in travelling by sea and air, and demands for the connection of moving craft with the world's telephone network, may in future limit the allocation of ether space to purposes for which no method of communication, other than radio, is practicable. In that case many of the services between fixed points for which radio is now employed may have to revert to the use of wires and cables.

Maximum Distance Conversations and Power Used.—As an illustration of the fact that the dimensions of the earth's surface now set no bounds to the range of telephony, it may be interesting to mention a long-distance test conversation carried out in association with the United States by two of my officers who visited Sweden last year in connection with the opening of communication between that country and America by means of the Anglo-American radio-telephone channels of the Post Office.

The chain of lines set up and spoken over on that occasion ran from Stockholm, via Berlin and Amsterdam, to London, and thence to New York by radio. From New York it was extended stage by stage via Chicago and San Francisco to Los Angeles, and back by another channel to New York, then once more to Chicago and back again to New York, with a final extension to the residence of one of the American Telephone and Telegraph Co.'s officials in New Jersey, from which a fair grade of conversation was exchanged with Stockholm.

The total length of the route traversed was about 14 000 miles, including approximately—

270 miles of open-wire line in Sweden;
200 miles in submarine cables across the Baltic and North Seas;
1 050 miles in underground cables in Germany, Holland and England, to London;
3 900 miles, London to New York, including the radio link of 3 200 miles and 700 miles in underground cables;
3 860 miles of open-wire line, worked by the high-frequency carrier system, and
4 850 miles in underground or aerial cables in the United States.

The aggregate length of copper conductor used on both sides of the Atlantic to carry this record long-line conversation would be about 40 000 miles.

The land-line equipment comprised 117 4-wire repeaters, 19 2-wire repeaters, 24 carrier-channel repeaters and 6 cord-circuit repeaters, in addition to 8 echo-suppressors and numerous other special devices. The total amplification of power included also that effected in the two radio transmitting stations, each of which has a power-amplification factor of about 100 millions, and at the two radio receiving stations which may be required to amplify the received power to any extent between 30 000 and 300 million times in order to compensate for the extremely variable ether channel at different times and seasons.

The power-amplification factor introduced at the radio transmitting and receiving stations—enabling the speech currents received over the land lines at the transmitter to be passed forward at the normal volume from the receiver to the land lines—will thus vary widely around a mean value of about 10^{16} (10 000 billions).

But the power loss made good by the repeaters on the wire-line portion of the circuit (11 000 miles) would be immensely greater. The transmission equivalent of the chains of circuits used would not be less than 2 400 decibels (240 bels) and was probably a good deal more. The relationship of power sent to power received over a circuit of 240 bels is a ratio of 1 to 10^{-240}.

It is permissible to think of the power which would be required to deliver currents of telephonic magnitude at the far end of such a circuit in the absence of repeaters. We start with an acoustic energy equal to about 10 microwatts delivered into the telephone transmitter by the voice of the speaker. The transmitter is itself an amplifier and delivers about 200 times this amount of energy into the line in electrical form—say 2 milliwatts. The receiver at the far end of the line will reproduce speech of minimum commercial volume with 1 microwatt. To deliver even 1 microwatt at the far end of a circuit of 240 bels without intermediate amplification, the initial energy must have the inconceivable value of 10^{231} kilowatts. I believe that the power radiated by the sun is of the order of 4×10^{29} kilowatts, from which it appears that the number of suns required to feed our circuit with the necessary power would be $0{\cdot}25 \times 10^{202}$. If we are inclined to accept Hubble's estimate that the maximum possible number of suns within the "world-line"—the limiting curve of space—is 2×10^{24} it follows that the whole radiant energy of nature would fall immensely short of meeting the requirements. We should need to multiply nature by 10^{177}—one might say "approximately"! It seems evident that the invention of the telephone repeater has tended to simplify certain problems!

The Photo-Electric Cell and its Applications.—The interesting phenomenon known as the "photo-electric effect"—the ejection of an electron from an atom by the absorption of a quantum of light-ray energy—which has assumed so deep a significance in fundamental physics, has also provided a new and extremely useful tool for the more materialistic purposes of the communications engineer. It may indeed be said that the invention of the photo-electric cell is comparable with that of the thermionic valve, in its power of achieving results which in its absence would have been beyond the range of possibility. Like the valve it has substituted the practically instantaneous response of the elementary processes of nature for grosser things. By its aid a pulsing beam of light, no matter how complex or how rapid its variations may be, can be made to produce an exact counterpart of its modulations in the form of an electromagnetic wave.

The photo-electric cell consists essentially of a light-sensitive element, usually an alkali metal such as potassium, used as a cathode from which electrons are ejected under the influence of light, and a separate electrode, maintained at a positive potential, which serves as an anode to collect the released electrons and conduct them into a circuit. The light-sensitive element is generally spread over the interior surface of a hermetically sealed glass bulb, leaving a clear window for the admission of the light. The anode is also contained within the bulb and has a grid-like structure so that, while allowing the light to pass freely, it will be favourably placed to catch and gather in the flying electrons. The interior of the bulb may be a vacuum, but the resultant current is considerably increased by the inclusion of an inert gas, such as argon or helium, at very low pressure in order to obtain the conducting effects of ionization of the gas molecules.

The electrical response of the cell varies in accordance with the wavelength of the incident light energy, being considerably greater to light near the high-frequency (violet) end of the spectrum than to the longer wavelengths, but, for light of constant character, it is directly proportional to the intensity of the beam.

Although the electrical energy obtainable from a photo-electric cell is necessarily very minute, it is sufficient to be successfully handled by modern methods of amplification, that is to say, it is well above the noise level introduced by the amplifiers themselves, provided that all possible screening precautions are carefully applied.

Time does not permit me to attempt any description of the methods by which this fascinating new tool is being used in the art of electrical communications. Within the past few years it has been utilized with great success in the development of apparatus for the telegraphic transmission of pictures, and of facsimiles of written messages and printed matter, both by wire and by radio.

It has brought practical television well on the horizon of coming events, and has also enabled the communications engineers of the Bell Co. to solve successfully the problem of combining the popular cinematograph with perfectly synchronized sound reproduction.

CONCLUSION.

In attempting to review the present position and course of electrical communications engineering within the compass of a short address, it is necessary to leave many aspects of the subject untouched.

I should have liked to say something about the interests of power and communication engineers in the avoidance of interferences between one system and the other, and of the widespread studies and discussions which are now going on with a view to devising means by which the lion and the lamb will be enabled to live together in peace and mutual satisfaction.

The general subject of submarine cables is also in a very interesting position, and the same applies to broadcasting—both by radio and by wire—and to the successful efforts which are being made to use simultaneously, for one purpose or another, every part of the frequency spectrum which wires and cables are capable of transmitting.

The automatic telephone system also presents many developments which are worthy of note, particularly in the direction of long-distance automatic switching and signalling, and in the design and utilization of really remarkable machines for automatically applying tests to the various parts of its intricate working plant, and facilitating its maintenance in proper condition.

There is much of interest, too, in the large programmes of line construction which are now being undertaken by telephone administrations all over the world, with a view to the building up of systems that will adequately meet the needs of the future, and be worthy to take their place in an efficient and reliable world system of electrical communication. The underground cable networks of Europe are becoming notably more impressive year by year, and they will be increasingly linked with the great systems of America, where the United States expects, within the next 5 years, to have the Southern States, and those of the Pacific and South Atlantic coasts, connected by all-cable circuits with the main cable network of the Eastern States and the States of the Middle West.

I feel, however, that I have already inflicted enough at one time upon this audience of general electrical engineers, and these and many other aspects of communications engineering may well be left to future opportunities, and, I hope, to many other and more competent exponents.

WIRELESS SECTION: CHAIRMAN'S ADDRESS

By Captain C. E. KENNEDY-PURVIS, R.N., Member.

(Address delivered 6th November, 1929.)

In this address I shall attempt to deal briefly with the progress of the art of wireless communication during the past two years.

One of the outstanding events is the fusion of wireless telegraph and cable interests by the merging of the communication side of the Marconi Co. with the Eastern Telegraph Co. Opinions as to the advisability of this are various, but the scheme has the approval of the Government and is now an accomplished fact. My own point of view is that this fusion is all to the good. Wireless telegraphy and cables are complementary to one another for long-distance point-to-point communication. It would have been little short of disaster for the cable services to have been completely superseded.

We are in an age of acute competition in communications, and every possible line must pull its pound. Cables have a distinct rôle in this, and after their long period of monopoly their owners are being forced by stress of circumstance to push on with developments and improve their technique. Some of these improvements may make the wireless world feel that cables are still a keen competitor.

We may now look forward to concerted development of Empire and world communications using both systems under one authority.

The Imperial and International Communication Co. has a link with the Governments of the United Kingdom, Dominions and Colonies through an advisory board of nominated members which has wide powers and can control the work of the company to a considerable extent, from the point of view of rates and service generally. There seems little doubt that there is a mass of traffic to be picked up if rates are made sufficiently low, and the cable and wireless technical staffs must so improve working and speed of traffic that rates can be cut and yet still pay. From the strategical point of view, cables are considered to be essential, and the merger saves these for future use in times of emergency or war.

The development of Empire and world communications by wireless telegraphy has shown satisfactory progress during the past two years. The original beam services to the British Dominions have continued to give an excellent and improved service, and the beam routes to South America and the United States are now well in their stride. Subsidiary lines by short wave to the smaller Colonies are being developed, and will develop much more quickly when the merger company has time to formulate its full proposals. Foreign nations are developing their own lines of world-wide communication, and competition among all nations to gather in traffic is acute.

While the use of short-wave working for long-distance traffic is advancing by leaps and bounds, I venture to put in a plea that the development of long-wave working should not be entirely abandoned. Congestion in the ether seems likely to be permanent; congestion will probably always be ahead of technique. As technique improves, additional lines will be started up and will overlap such improvement as may be effected from time to time.

It will be foolish to desert the lower frequencies without exploiting them also to the uttermost. In time of war, even if we are neutral, it may be found that short-wave working becomes exceedingly difficult; a nation at war will not care much for conventions, and those countries which have continued to use a long-wave service and their cables will have an advantage.

Radio telephony has made very great strides and has now reached the stage of being a sound commercial proposition. Commercial telephony over long distances was first made possible by the British Post Office in conjunction with the American Telegraph and Telephone Co., with the result that Great Britain is the centre for Europe of the North American transatlantic service. By the judicious use of long and short waves a 24-hours service is possible, and four separate channels are available.

Other countries have since advanced with more or less success, and some services now opened are Holland to Java; Germany to Siam and Buenos Aires; France to Buenos Aires; and Spain to the United States and Buenos Aires.

Experiments in multiplex transmissions whereby one carrier is made to do duty for one or more channels of telegraphy as well as telephony show signs of promise, but it is rather a question whether the wave-band occupied by such methods at present is not considerably wider than the sum of the wave-bands which would be used by an equal number of separate stations.

Cable companies are not lagging behind; a cable capable of telephony and high-speed telegraphy across the Atlantic is likely to be put into service before long.

Turning to broadcasting, the difficulties which arise between different nations as to their requirements are now in a fair way to be considered as settled, at least for a time. There are more than 150 broadcasting stations operating in Europe alone. It is easy to see that without very careful organization there must be serious interference over the whole of Europe. The recent agreement of 27 European nations to the Prague Plan for the allocation of wavelengths was a notable step in the right direction.

This Plan is the culmination of four years of work at the Union Internationale de Radiophonie. As early as 1924 it was realized that international agreement and co-operation were essential if the rapid increase of the number of European stations was not to result in a state of complete chaos. This was due to the fact that the majority operated on wavelengths below 500 m, and that, although the range of the ground wave may be limited, under certain conditions the range of the indirect wave may cause interference at a very much greater distance.

Two international plans preceded the Prague Plan—the Geneva Plan of 1926 and the Brussels Plan of 1928. These two plans were successful in so far that friendly agreements were come to by responsible authorities to operate their stations on certain wavelengths. They suffered from the disadvantage that they were not agreements between the Governments of the various nations, and there was therefore no method of securing adherence to them.

The Prague Plan was a great advance on its predecessors in that it is an agreement between Governments and can thus be enforced. Although the allocation of wavelengths has been much criticized it was obvious that some such plan was necessary, and there had to be a certain amount of give and take. Nations who were early in the field, e.g. Great Britain, France and Germany, suffered somewhat on the re-allocation of wavelengths, but this was in a good cause. The establishment of an international wavelength checking post at Brussels was also a step in the right direction.

One important point which will soon require settlement is the encroachment of long-wave broadcasting on to the wave-band allocated for use by aircraft.

In Great Britain, interest has been aroused amongst the public by the Regional Scheme under which the country is to be served by a series of twin high-power stations located at selected points outside certain cities. The recent opening of the new station at Brookman's Park marks the beginning of this scheme. The underlying principle is to give to every listener an alternative programme, whilst to many listeners with selective sets it will provide several alternative programmes. In addition it will give a maximum of field strength over the larger cities where local interference is caused by trams and other electrical machinery. It carries with it, however, one drawback, viz. a probable " wipe out " area close to the station from which it will be difficult to receive anything but the local transmission and in which the listener may experience difficulty in separating the two local programmes if the simpler types of receiving sets are used.

Communication with ships must always interest a country which depends on ships for its existence. Services to and from ships have steadily improved. High-speed working in the case of big ships of the western ocean trade, and short-wave working for very long-distance communication, have developed. Long-wave working for medium distances has also shown advance.

That bugbear to broadcast listeners—" spark "—is being gradually scotched by the introduction of interrupted-continuous-wave working at all Post Office coastal stations. It remains for other nations to follow suit. An interesting point in this connection is the use of different note frequencies by each British coastal station in order to avoid congestion of traffic, it being a fairly simple matter to over-read or under-read the signal required from the interfering signal.

Let us now consider the theoretical advances which have been made. A very considerable addition has been made to our knowledge of the theory of the propagation of waves, notably by research work carried out in England under the auspices of the Radio Research Board and by the Marconi Co.'s research staff. This work has been described in papers read before the Wireless Section, and the earlier theories of Eccles and Larmor regarding the mechanism of wave propagation have been largely confirmed by the experimental work of Appleton, Eckersley and Hollingworth. The work done has shown that, whilst normally the long waves are plane-polarized, an important change occurs in the medium waves of the higher frequencies which may have downcoming components the polarization of which differs from that for the surface wave. The long waves travel over the surface of the earth, whilst the higher-frequency waves in the medium band not only travel over the earth's surface but have indirect components which are free from the earth and are modified by the Heaviside layer. A combination of the surface and indirect components of the medium waves may produce very serious night errors in direction-finding, and fading due to the interference of these components also occurs.

As regards the short-wave band, very valuable evidence has been obtained on the fading of wireless signals. This has been dealt with very fully in a recent paper read before the Wireless Section. Experimental work indicates that the Heaviside layer is a complex structure of electron clouds or strata, and when a group of electromagnetic waves at the frequencies of the short-wave band enters the layer the following phenomena occur:—

(1) *Scattering of the radiation.* This is evidenced in a remarkable manner by the fact that, for the case of the Marconi short-wave beam transmitters working to

a receiving station, direction-finding observations taken at distances close to the transmitter and within the skip zone give the bearing of the place where the beam enters the Heaviside layer, which corresponds to the great-circle bearing of the receiving station.

(2) *Fading of signals.* This arises from the complexity of the layer and the fact that, in addition to their purely free irregular motions, the electrons may also have definite motions due to the magnetic field of the earth. A plane-polarized wave entering the layer must ultimately be resolved into at least two circularly polarized waves travelling with different velocities, whilst for the case of a group of waves such as go to make up a signal, different parts of the group will also have different velocities. The various fading effects may be considered to be due to:—

(i) *Rotation* of the plane of polarization of the combined result of these circularly polarized waves, due to slight changes in the magnetic field.

(ii) *Interferences.* There seems to be experimental evidence that the waves reaching a receiving station may have traversed paths of very different lengths. These can interfere with one another and thus produce fading. Some of these have suffered only a single reflection in the Heaviside layer, while others have suffered multiple reflections between the Heaviside layer and the earth. The term " reflection " is here used in a very general sense to indicate that the wave has been bent back to the earth by the Heaviside layer. Calculation shows that modulation of the transmitted waves should reduce fading from this cause, and recent tests indicate that this is actually the case.

(iii) *Scattering.* When scattering is present, further fading effects are thereby caused.

The methods employed in short-wave reception for mitigation of the effects of this signal fading include the use of spaced aerial arrays and long horizontal aerials of the Beverage type. In addition, circuits have been developed with a view to obtaining increase of sensitivity for weaker signals, e.g. the use of grid bias the value of which depends on the field intensity at the receiving aerial.

The research work and experimental observations which have been made on the Heaviside layer, and on which papers have also been read before the Wireless Section, have indicated that there are two or more regions where changes occur, the two main regions being at heights of the order of 100 and 250 km respectively.

The problems underlying this work have been very largely tackled by the employment of suitable signal intensity and direction-finding apparatus which has also been described before the Wireless Section, and this work has resulted especially in a very considerable development of aerials and apparatus suitable for short-wave direction-finding, these aerials being based mainly on the type originally proposed by Adcock, in which the receiving aerial system is so designed that it is unaffected by any horizontal component of electrical force.

As regards the possibility of taking direction-finding bearings on short waves, valuable evidence illustrating the limitations has been published. The direction-finding observations which have been made on distant and near stations have tended to confirm the general correctness of our ideas regarding the Heaviside layer and wave propagation therein. Summarizing the results from these observations the following broad conclusions are obtained:—

(1) It is reasonably possible to locate by direction-finding apparatus a very near-by transmitting station where the ground wave preponderates.

(2) If the distance is such that the point of observation is within or close to the edge of the skip distance then the whole of the effects are due to scattering and either little or nil bearing, or an enormous error, is observed.

(3) As regards the distant transmitting stations, (*a*) If the distance is so great that in general a single indirect ray only is being received, bearings are reasonably accurate. (*b*) Even at very great distances, however, though bearings definitely in error are not frequent, there are some occasions on which nil or indistinct bearings are obtained, owing doubtless to either (i) a multiplicity of waves following different paths, or (ii) interference arising from scattering.

Our knowledge of the echo effects produced at a receiving station on the shorter waves (which may give rise to mutilation of signals) has been increased, and records have been taken with the cathode-ray oscillograph showing the arrival of waves which have travelled several times around the earth's perimeter.

A very interesting phenomenon is the arrival of echoes after a very long interval of time, and intervals of 15 seconds have been observed by continental research workers.

Whilst some workers are of opinion that these echoes are due to special conditions in the Heaviside layer enabling the waves to pass many times around the earth, there is no adequate explanation at the present time of how the great attenuation that one would expect in such cases is overcome. An alternative explanation is that these waves have penetrated the earth's atmosphere and have been reflected back by swarms or bands of electrons in space. This view has been put forward by C. Störmer.

The echo phenomenon observed in short-wave reception has led to the development of directive aerial systems tending to reduce the mutilation which the echoes otherwise cause.

Taking next the development of the use of long and medium waves, the valve thermionic generator is continuously displacing the other and older systems of high-frequency generation. It is only on the longer waves that the high-frequency alternator and arc systems are still being employed for point-to-point services, and the tendency is to reduce the traffic hours of these long-wave systems by supplementary valve short-wave systems.

Advance has been made in the way of stabilizing emissions, which in these days of congestion is a necessity.

As regards broadcasting, an enormous amount of hard technical work has been necessary to produce the extremely good quality of the B.B.C. transmissions.

I have mentioned the Regional Scheme earlier in this address. From the technical point of view, perhaps the most interesting development which the regional scheme renders necessary is the placing of all the so-called relay stations on the same wavelength. This proposal has brought with it the great problem of obtaining isochronism of the carrier wave of all the stations, and the success of the scheme must depend largely on the solution of this problem. So far it has been attacked by the use of tuning forks as the fundamental standard from which the carrier waves are built up by frequency multiplication. Apart from the disadvantage of the complicated amplifier system for frequency step-up, this method appears to give the required degree of accuracy. The advance being made in the technique of quartz-crystal control may ultimately, however, offer an alternative solution.

Short-wave development has been very rapid, whilst the short-wave beam and similar services have been well maintained. The main development of short waves has been in regard to the great extension of the use of waves in the higher-frequency regions between 15 000 and 21 000 kilocycles per sec., which band of frequencies has been found effective for long-distance communication during daylight hours.

Still higher frequencies have been used with a certain amount of success but, in general, it has been found that the results obtainable at frequencies from 21 000 to 30 000 kilocycles per sec. are subject to very heavy fading. During the cruise of H.M.S. "Yarmouth" to the Far East, commencing December 1925, good communication was occasionally established with Horsea as far as Hong-Kong, using a frequency of 25 000 kilocycles per sec. The Marconi Co. have obtained results across the Atlantic, using a wave of 8·67 m (34 600 kilocycles per sec.).

In regard to the frequency band between 15 000 and 21 000 kilocycles per sec., the results obtained have shown that the hours of working vary considerably with the season, but the development of these waves has enabled communication to be obtained at long ranges over a very large proportion of the 24 hours by the judicious change of frequencies at various times of the year. The success obtained with this frequency band is due not only to improvements in transmitting circuits and valves, but also in considerable measure to the adoption of special forms of directive aerial systems which have been found very efficient for radiation at these frequencies.

Apart from the Franklin vertical arrays as used by the beam stations, the most generally used types for these frequencies are perhaps multiple arrays of horizontal or vertical dipoles, but some interesting systems have also been developed in France by Mesny and Chiveix in which the array comprises wires arranged to form either a double zigzag or a Grecian Key curtain, and for long-range working multiple arrays erected on low masts of height less than 150 ft. have given satisfactory results.

Commercially, as regards the type of aerial array for a given service, it seems to be a problem of balancing power input and its cost against the cost of masts.

The Marconi Co. have developed their beam system for operation on this higher-frequency band, and considerable work has also been done on the Continent. For example, a service with South America is maintained by Germany, and the Dutch Government has developed a very considerable communication service between Holland and Java, using frequencies of the order of 18 000 kilocycles per sec. for day work and 10 000 for night work, variations in frequency being made from time to time as found necessary owing to the seasonal changes.

During the European summer period, particularly about June, practically continuous communication is maintained throughout the 24 hours of the day using these higher frequencies only. In winter time the higher-frequency communication is limited to some 4 hours of the day, but the lower-frequency period can be carried on for approximately 12 hours. For the communication by Germany with South America, frequencies of the order of 16 500 and 11 500 kilocycles per sec. are employed.

The Admiralty have for some years been working a service to the East (Hong-Kong and Singapore) on 8 570 kilocycles per sec. This service has now been supplemented by a day wave service working on about 18 000 kilocycles per sec., and during June of this year a 24-hour service was maintained with Singapore on the latter frequency. During the winter months, however, the possible service is much reduced, but the daily hours of communication can then be augmented by the use of frequencies of the order of 13 000 kilocycles per sec.

Other interesting applications of short-wave working have been the use by the British Post Office of short waves of the order of 19 000 kilocycles per sec. for the transatlantic telephone system as an alternative to the long-wave transmission, and the short-wave broadcasting programme on 12 500 kilocycles per sec. which has been carried out from Chelmsford. In addition, in Holland a short-wave transmitter has been installed near Hilversum with the object of broadcasting direct to the Dutch East Indies on the daylight wave-band.

All the above developments refer to point-to-point or to broadcasting services, but there has been a very considerable development in the use of short waves for mobile services both for naval working and for the mercantile marine. As regards British naval services, practically all H.M. ships have been adapted for short-wave working.

Satisfactory results have been invariably obtained on the lower frequencies usually employed for the night services, but it is not so easy to obtain satisfactory results on the daylight wave-band and the difficulties are at present not entirely overcome. Although the use of short waves for mobile ship services is proving of great value, there is a certain limitation to its use, due chiefly to the zone where either interference is experienced between the surface and indirect radiation from the transmitter, or there is a definite gap between these components of the transmission.

This "skip zone" has been observed at sea on all frequencies above 6 000 kilocycles per sec. at varying distances below 1 000 miles. The lower-frequency band between 6 000 and 4 000 kilocycles per sec. has been found to be very much better in this respect, but it cannot be said that short waves will meet the requirement of a continuous service for ranges up to 1 000 miles at sea to the same degree of reliability as long waves.

Apparatus Development.

As regards the obtaining of H.T. power supply for transmitters, the high-tension d.c. generators for the Rugby long-wave high-power station have now been in operation for some years and have given very satisfactory results. The British Broadcasting Corporation are also using high-tension d.c. power, for example in their 5GB station, with satisfactory results.

The alternative systems of H.T. supply by means of single-phase or multi-phase rectifier systems are, however, in more general use for the medium-power transmitters, and especially is the use of double 3-phase rectification in favour. It has been claimed that the rectifier systems give greater security and reduced tendency to flash-over of valves. On the other hand, figures have been published showing a considerable economy resulting from the use of high-tension d.c. machines for fixed station transmitters.

For the high-power medium- and long-wave transmitters, the metal-glass valve with suitable cooling agents, such as distilled water or oil, has become well established; the silica radiation valve has also shown itself to be a very economical means of generating oscillatory power up to 10 and 20 kW, especially where the space is limited. Considerable experimental tests on metal-glass valves of increased anode rating have been carried out by the Post Office engineering staff at Rugby, but the development of higher-power standardized valve units capable of being used in parallel is proceeding more slowly than at one time appeared probable.

The development of the daylight wave-band of frequencies for short-wave service working on long ranges has increased considerably the technical problems connected with transmitting valves and circuits. The inherent capacity of the valves imposes a limit to the permissible inductance and, in practice, it is a matter of extreme difficulty to design stabilized transmitters for these very high frequencies. As regards the metal-glass valves, there is an increased danger of puncture of the glass envelope; this is usually guarded against by fitting an annular ring as an internal guard-ring device to screen the seal joint of the metal to the glass envelope.

In this connection it may be of interest to record that, as regards high-power valves used for Admiralty services on these frequencies, very considerable success has attended the use of the water-cooled silica valve the development of which has been described before the Wireless Section, and two of these valves are in regular operation handling from 20 to 30 kW for Admiralty services to the Far East on frequencies of the order of 18 000 kilocycles per sec.

The ability of the silica envelope to withstand very high voltages at frequencies as high as 30 000 kilocycles per sec., without danger of puncture, renders it peculiarly suitable for the generation of oscillatory power on these higher frequencies.

The increase in wireless telegraph services is bringing with it an ever-increasing tendency to greater stringency as regards frequency control of transmitters. The tuning-fork method of control has now been in use for some considerable time in this country, e.g. at the Rugby high-power long-wave station and at various stations of the British Broadcasting Corporation, and this has proved an excellent system of high constancy.

As regards short-wave transmitters, the very large number of stages which would be required for tuning-fork control of the short-wave band of frequencies is naturally a disadvantage and, for this reason, the short-wave transmitters are controlled in frequency either by well-designed short-wave master control circuits as used by the beam stations, or by the use of quartz crystals. The quartz crystals employed have usually a fundamental frequency of the order of 2 500–3 000 kilocycles per sec., and stabilized transmitters taking H.T. inputs of 30 to 50 kW at their final stage are in operation using frequencies up to the sixth harmonic of the quartz crystal.

The use of quartz may perhaps not give such a high constancy of frequency as that which is obtained from tuning-fork control and, owing to the number of modes of vibration, care has to be taken to ensure that maximum control is obtained on the correct frequency. It does, however, operate exceedingly satisfactorily when the amplifying circuits are properly tuned and neutrodyned, and is capable of giving a continuous-wave note of excellent quality even for the case of relatively poor regulation of the H.T. and filament power supplies for the transmitter, or when a.c. supplies are used for the filaments.

There is usually a change of frequency with temperature of the order of 30 parts in 1 million per degree C. with the use of quartz crystals, and for this reason thermostatic controls are used, but it has been claimed by certain experimentalists that careful selection of the quartz cuts may reduce this variation to the order of 2 parts in 1 million.

Turning to the development of receiving apparatus, there has been very marked advance in connection with the design of broadcasting receivers and their components, and the apparatus sold by the great majority of British firms is of excellent quality and most reliable in operation.

There has been a gradual change in the type of set offered to the listening public by the manufacturers, consequent on the introduction of two new valves to the market, i.e. the screened-grid valve and the pentode. The large amplification factor of the former and the large mutual conductance of the latter have made it possible to build up relatively cheap sets using only three valves and having a performance at least equal to that of the more ordinary types of sets employing four 3-electrode valves. From an operating point of view these sets gain in ease of handling, but they need careful construction and screening in order to function properly.

The moving-coil loud-speaker has also made great progress, and there has been a general development of power amplifying valves which has resulted in greater demands being made upon the high-tension supply of broadcast sets. This has led to improvements in dry batteries, but principally it has led to the development of highly successful battery eliminators.

Apart from receiver broadcasting developments, the chief technical development work has occurred in connection with the use of short waves, where a large number of problems have arisen for solution. Especially was it soon realized that for satisfactory short-wave reception the screening between the various parts of a receiver must be much more perfect, to be effective, than for the case of long waves, and that special precautions were necessary to prevent back-coupling from battery leads and what were formerly regarded as earthed leads.

The past two years have seen the commercial development of various remarkable types of screened-grid valves, and valves with amplification factors of over 1 000 are now available. At the same time these valves have a relatively small anode-grid capacity compared with that of the 3-electrode valve.

Despite the introduction of the many new and improved valves it is, however, fair to say that for frequencies above, say, 8 750 kilocycles per sec., only slow progress has been made in the development of a system of genuine high-frequency amplification, and for these higher frequencies the most successful methods of reception are still (i) the detector valve with reaction followed by note magnification (the quenched type of receiver may be regarded as a modification of an oscillating detector), and (ii) the super-heterodyne.

For work in the Navy both these methods have obvious disadvantages, since in their simplest forms they involve oscillations in the aerial with consequent interference between ships in close order receiving the same signal.

The use of detector valves in "push-pull," and special methods of feeding-in the heterodyne, do much to reduce the difficulty in the case of the super-heterodyne type of receiver.

In the case of the detector valve with reaction, however, removing the reaction from the aerial tends to reduce the efficiency of the receiver to a very great extent. It is in this connection that modern screened-grid valves have proved of great value, for it has been found possible by the use of one of these valves in front of the detector to make up to a great extent for the loss involved in removing the oscillating circuit from the aerial. This make-up can hardly, however, be regarded as true high-frequency amplification, since what amplification is obtained depends almost entirely on the fact that the anode circuit of the screened-grid valve is oscillatory, and the addition of further stages between the valve and the aerial in which reaction is not applied may even result in a loss of signal strength.

OTHER DEVELOPMENTS.

The extensive research work which has been done over a considerable period, in connection with the high-speed transmission of pictures and print by wireless telegraphy, has borne considerable fruit, and the Marconi Co. have applied this to the short-wave beam stations for services working between the United States and England. In the system which they have developed, a source of light, which is mechanically interrupted, explores the surface of the message forming the interior surface of a cylinder. The light scattered from the message surface is collected and arranged to fall on a photo-electric cell the output of which modulates the wireless transmitter. The output of the wireless receiver is applied to the electrodes of a Kerr cell, which controls the light intensity falling on sensitive paper. The necessary synchronization is obtained by separate tuning-fork control. Means for phase adjustment of the message cylinders at both transmitter and receiver ends are also provided.

The Fultograph system has also been developed for the broadcasting of pictures of current events, and the B.B.C. have a regular service of this system for pictures and for weather charts.

As regards the transmission of living pictures, broadcasts by the Baird Television Co., Ltd., are now being made for $\frac{1}{2}$ hour daily for 5 days a week, and in this connection it is interesting to note the development by them of synchronization between the transmitting and receiving apparatus by utilizing electromagnetic control obtained from the current forming the picture elements.

Another branch which is undergoing considerable development is that in connection with radio beacons for direction-finding at sea and for navigation in bad weather. In general, it is doubtless the best policy for ships to be fitted with suitable direction-finding receiving gear capable of giving accurately the position of fixed transmitting stations on land, and the tendency is for the ships fitted with direction-finding apparatus to increase in numbers. Not only can the observations of special shore station transmitters along a coast be taken, but in certain cases other shore stations may be observed to give cross-check bearings.

An alternative system which is undergoing trial is provided by the rotating beacon developed by the Royal Air Force, which employs a vertical closed-loop transmitter arranged to rotate about a vertical axis. The full intensity in any direction will depend on the position of the plane of the coil, the signal being a minimum when the plane of the loop is at right angles to the great-circle bearing. In this case no apparatus beyond a simple wireless receiver and an accurate stop-watch for the ship is necessary, and when the plane of the coil is perpendicular to the geographical meridian a special signal is sent out by the beacon and the observer on board ship starts his stop-watch. As the beacon rotates, the intensity of the received signal will vary and finally pass through a minimum value at which instant the plane of the loop is at right angles to the great-circle bearing. By observation of the time interval the bearing can be obtained by a simple calculation, since the beacon is revolved at a definite speed. These stations have a definite value not only for coastal ships and ships not fitted with direction-finding sets, but also for aircraft. An experimental beacon of this type has been erected at Orfordness and is giving excellent results.

In addition to the rotating beacon system, the Marconi Co. have developed a fixed aerial beacon system which sends out a recognized signal at convenient intervals to enable ships fitted with direction-finding apparatus to take bearings. They have also designed their system to operate in conjunction with synchronized signals from submarine signalling apparatus so that the ship can, from the observed time difference between the wireless and submarine signals, obtain the distance of the ship from the beacon transmitter as well as the bearing by the use of direction-finding receiving apparatus.

A further navigational development, which rather resembles the synchronous signal idea, is to transmit a radio-telephony signal through a microphone adjacent to the siren of a lightship or lighthouse. The operator first hears the siren in his head telephones and later the air-borne sound, the time interval giving the distance. This system is actually under trial on the Clyde.

WIRELESS TELEGRAPHY IN THE MERCHANT MARINE.

The Washington Convention of 1927 has had a good effect in forcing the gradual elimination of spark sets in ships. By this Convention no new spark set may be installed of over 300 watts after January 1930, and all existing spark sets must be reduced to 300 watts by 1940. The result of this is to cause shipowners to fit interrupted-continuous-wave and continuous-wave sets of modern design. The large ships now usually carry a set of about 2 kW capable of use on continuous waves over a wave range of 1 000–2 650 m and on interrupted continuous waves over a wave range of 600–800 m. Smaller ships are now being fitted with ½-kW interrupted-continuous-wave sets to cover the 600-m neighbourhood.

Short-wave sets are growing in popularity and are usually fitted to work off the long-wave rectifying panel. Communication over some part of the 24 hours is possible from any part of the world with either the Post Office short-wave station in this country or the United States, or both. A daylight wave of about 26 m and a night wave of 36 m are commonly used.

Certain services which are required in the big Atlantic passenger liners are of interest. One of these is the "brokerage" service. This implies an independent service which must be free from interference from, and must cause no interference with, the ordinary wireless telegraph traffic of the ship. This is not an easy problem to solve, but the difficulties have been overcome. Quotations are received normally on long waves from Tuckerton and New Brunswick, but transactions are carried out on a short-wave service which is entirely independent of the ship's main installation and is fitted in a separate office.

Direction-finding apparatus has been further developed, chiefly in the direction of reduction of space required for aerials and in increase of wave range. The number of ships fitted shows a very great increase.

ORGANIZATION TO LIMIT CONGESTION.

The remarks which I have made regarding the very large development of services on all bands of frequencies indicate how the overlapping of services is tending to increase the resultant interference. This has received a good deal of illumination at the recent meeting of the International Radio Technical Committee held at the Hague during September last, and I propose to quote a few of the agreed items. This Committee, known as the C.C.I.R., is intended to fill in the gap between main meetings of the International Radio Conference, of which the last was held at Washington in 1927.

The findings of the C.C.I.R. are not binding on any Governments but are intended to be advisory. Any recommendations it may make can only be brought into force at the next meeting of the International Conference. There will be a meeting at Madrid in 1932 of the Radio Conference, where matters which have been raised by the C.C.I.R. will come to the forefront.

The recent meeting at the Hague was attended by representatives from practically all nations, including Russia. The agenda of the meeting was confined strictly to 16 questions, which had been previously circulated. I propose to touch on certain of these questions which are of more general interest.

Question (2) raised the evergreen problem of how the power of a transmitter is to be measured. It is recommended that the power of the transmitter should be understood as meaning the power in the aerial itself; methods to carry out this measurement were included.

Question (3) dealt with the definitions of long and short waves. These definitions are, of course, quite arbitrary, but it is well that the different nationalities should understand what is meant by the various terms.

The definitions were fixed as follows:—

	kilocycles/sec.	m
Long waves	Below 100	Above 3 000
Medium waves	1 500 to 100	200 to 3 000
Intermediate waves ..	6 000 to 1 500	50 to 200
Short waves	30 000 to 6 000	10 to 50
Very short waves ..	Above 30 000	Below 10

Questions (5) and (6) dealt with wave-meters, standards of frequency, admissible tolerances and monitoring. It was decided that no absolute international standard of frequency is practicable at present. It is left to each nation to establish its own standard, and to arrange for comparisons with other countries.

Recommendations for tolerances for the various orders of wave-bands at different types of stations are made. The tolerance is defined as the maximum admissible departure from the nominal frequency notified to Berne and the mean frequency actually transmitted, the difference being due to (i) the error in wave-meter or control circuit; (ii) the error in adjustment at the station; and (iii) the "drift" during transmission.

No account is taken of the modulation. The tolerances agreed to at present for short waves are as follows; these are of the most interest:—

For waves of 6 000–23 000 *kilocycles per sec.*:—

Fixed stations	0·05 per cent
Land stations	0·1 per cent
Mobile stations	10 kilocycles per sec.
Fixed and land stations of 250 (or less) watts output ..	10 kilocycles per sec.

The tolerances for the future, at some date not given but as soon as technique allows, are respectively 0·01 per cent, 0·02 per cent, 5 kilocycles per sec., and 5 kilocycles per sec. These tolerances apply only to fixed and land stations whose waves are actually notified.

In the case of mobile stations the right to use any wave of the bands applicable was agreed to.

It was agreed that each nation should establish a national laboratory with a national frequency standard, each country to monitor frequencies of its own stations.

In this country the N.P.L. standard will be regarded as the normal standard, and the Post Office will do the necessary monitoring.

A "pious hope" was expressed that countries would hasten the abolition of spark, even before the date fixed by the Washington Convention.

Questions (7), (8) and (14) dealt with the channelling problem. The channelling scheme itself was not agreed to, but the Committee drew up certain recommendations necessary in order to prevent chaos in allocation of wavelengths. These briefly are:—

(1) In the reserved fixed service bands below 50 m, frequencies allotted in kilocycles should be divisible by 5. It was agreed that a separation of 5 kilocycles is not always sufficient at present but that actual practice shows a separation of 0·1 per cent to be practicable.

(2) Certain definite particulars should be forwarded when notifying waves. This was intended to stop premature wave-appropriation, but whether it will do so or not remains to be seen.

(3) Indicates the frequency band width (in cycles) occupied approximately by various forms of wireless transmission.

(4) Stresses the necessity of selective reception.

(5) Deals with the question of the use of short waves, of different orders for various distances. Final recommendations were:—

  (*a*) Waves between 50 and 13 m should be reserved for long distances, but these may be used for moderate distances from 2 hours after sunrise until 2 hours before sunset.

  (*b*) Waves between 50 and 85 m would be reserved for moderate distances.

  (*c*) Waves between 85 and 200 m would be used for the shorter distances.

These recommendations refer to point-to-point working only, and are only put forward as a general principle.

(6) Draws attention to the importance of stations which use the shared bands employing modern apparatus, having regard to the number of stations which are likely in the near future to operate in these bands.

Question (15) dealt with the limitation of power of broadcasting stations, and it was recommended that the power of European broadcasting stations using waves between 200 and 545 m be limited to 100 kW. Russia was excepted from this recommendation at her own request.

As regards stations using waves above 1 000 m, the liability of interference with air services was considered and certain articles of the Washington Convention were reiterated which forbid any increase of power of long-wave broadcasting stations if such increase should cause interference with existing services.

Some Problems of the Immediate Future.

One of the most interesting problems is to determine what application can be made of the band of higher hertzian frequencies of the order of 30 000 kilocycles per sec. and above. At the present time they are mainly employed for such purposes as rotating beacons for ship navigation and for short-distance communication, but further developments of aerial and reflector transmitting systems, together with receiving apparatus, may make them suitable for highly directional communication systems.

In regard to the receiving problem on these waves, it is important to emphasize the need for valve development in which the inter-electrode path is reduced to a minimum; for the time of flight of the electron at the higher values of these frequencies, such as those of the order of 300 000 kilocycles per sec., is comparable with the period of oscillation.

The work of the C.C.I.R. to which I have referred brings out the necessity of aiming at the highest possible degree of frequency stabilization and reduction of permissible tolerances to admit of an increased number of services without interference. In this connection the importance of developing suitable monitoring stations and apparatus for the checking and setting of transmitters to definite frequency values cannot be overestimated. It is interesting to note that at the present time the technique of frequency control of short-wave transmissions approximates to the accuracy with which the absolute value of the frequency can be measured.

The further development of receiver control, for example the method of "gain control" used at the present time for counteracting the effects of fading, is an urgent requirement for short-wave services. The development of the screened-grid types of valves having better effective screening might lead to considerable improvement as regards amplification and to better performance results on the shorter band of wavelengths.

Turning to the atmospheric interference problem, as regards long-wave reception the improvements of receivers with a view to reducing this have been small, and this interference is still an outstanding difficulty. Advantage has, however, been obtained indirectly by the use of the higher frequencies of the short-wave band, where the atmospheric interference problem is not so serious.

The development of single-unit thermionic valves for the generation of very high powers is not proceeding so fast as was at one time to be anticipated, and considerable development work is still required. As regards the receiving valve, it would appear that there is still room for improvement in connection with the reduction of microphonic noises.

METER AND INSTRUMENT SECTION: CHAIRMAN'S ADDRESS

By E. W. Hill, Member.

"ELECTRICITY METERS."

(*Address delivered* 1st *November,* 1929.)

I appreciate and acknowledge the great honour that this Section has conferred upon me in electing me its Chairman. I earnestly desire to do all in my power not only to maintain the dignity of the office I hold, but to make the activities of this Section interesting, useful, and of a nature to reflect credit on the Institution of which this Section is a constituent part. I am very pleased indeed to say that the Section is in a healthy and flourishing condition. We have had a very successful first session with a number of papers of considerable merit. In addition we have a full syllabus of important and interesting papers for this session, with an overflow into next session.

Memories, still vivid no doubt, of the late Meter Engineers' Technical Association even now linger among us, especially among those who helped in its inauguration and its subsequent development. After two years of remarkable progress that Association, which was plainly growing into the full efflorescence of its development, was called upon, by circumstances and by a call that could not be disregarded, to make the greatest sacrifice it could be called upon to make, namely its own extinction. It made that sacrifice, as you all know; it offered itself up for the common good, and became substantially the nucleus of this Section. That transformation, and its results, should be a source of pride for us. It is true that some regrets have been voiced. There are those who thought, and perhaps still think, that the junior members of the old Association are not participating in the benefits of this Section owing to the difficulty of absorbing them within the Institution membership. A project has even been mooted for forming a new association mainly for the benefit of juniors. The advocacy of this project has been able enough, but to my mind the pleadings, plausible though they be, are fundamentally unsound. Anyone, junior or otherwise, who gave support now to such proposals as those for a separate association, would be tending deliberately to deprive himself of the benefits that are available to him within this Section. The members of such an association would run the serious danger of becoming self-centred. One of the collateral advantages of membership of the Section for the juniors is the definite incentive to them to improve their technical knowledge for the sake of advancing their grades in the Institution; and in these days technical knowledge, as complete as it is possible to acquire it, is an almost indispensable condition for material advancement. Juniors will do well to ponder over this point. They will do well to have as high an aim as possible. The Institution provides at once the aim and the almost indispensable means of achieving it. It offers also unique opportunities for those who wish to seek contact with the best that is being thought and practised in the sphere of their professional interests. If these things involve for some the surmounting of difficulties, surely nothing is better as a discipline for the character.

Nobody, I imagine, will be surprised, in view of my personal predilections, and in view of the impossibility of covering the whole field of electrical measuring instruments, at my choice of the subject of my address, namely "Electricity Meters."

It is a curious reflection that electricity meters must have been allowed by default to be named on the paradoxical principle of *lucus a non lucendo*—the same principle that leads us to call "up"-lands "downs." Water meters measure water, and gas meters measure gas. Electricity meters, however, do not measure electricity. The elusive electrons can, it is true, be numbered, but the electricity meter does not do it—at least not expressly. What matters, and what is measured, is not alone the number or the quantity of electrons engaged, but something more important and fundamental, namely their activity while they execute the tasks imposed on them by man's ingenuity. Their activity is evaluated by the amount of work they accomplish, or by the amount of effort and expense incurred in urging them to do this work. In short, it is energy that is measured, and our science might well have been called "electric energetics." I would not of course labour this very obvious point did I not wish to direct attention to something beyond a mere defect in nomenclature. Our meters, as I have said, are required to measure energy. Energy, apart from the ultra-refinements introduced by the very latest ideas of modern physics, is, as far as engineers are concerned, a perfectly straightforward scalar quantity. It is an *amount*. It is not, one would think, an awkward thing to measure like a velocity or an acceleration, which are *rates* or derived quantities. That being so, we ought to be able to measure it accurately, or at least accurately enough to leave us free from introspective and continual preoccupation about possible lack of accuracy. We seem like invalids, constantly preoccupied about their lack of health. We are obsessed with this question of accuracy tolerances. We have had a society formed for the "promotion of accuracy in metering." We have had British Standard Specifications framed after much difficulty and labour and some contention. Manufacturers compete most keenly to provide meters more accurate than those of their rivals instead of being able to say "our meters are accurate with a negligible margin of tolerance."

In power station plant-tests it is well known that practically all the quantities requiring measurement on the input side can be measured with greater accuracy than the electrical energy output. Other kinds of electrical measurements can, even with commercial grade instruments, be made with great accuracy. Time measurements can be made, even with a very mediocre clock, to an exceedingly high degree of exactness. Even a foot rule can be used to measure with an accuracy of 1 part in 1 000. Other branches of science offer impressive examples of excessive accuracy. The astronomer can directly measure star parallaxes as small as 0·75 second of arc with certainty, which is the angular diameter of a halfpenny as seen at a distance of 4¼ miles; by photographic methods 0·01 second of arc can be measured. Heat radiation as feeble as that equivalent to the effect of a candle flame at a distance of 100 miles can be measured by sensitive bolometers. Naturally we must beware of confounding sensitivity with percentage accuracy. But the moral is obvious, and provokes the question: " Is there something fundamentally wrong with our methods of measuring electrical energy? " Should we in this respect submit ourselves to a course of self-examination, with confession and repentance to follow, and an amendment of our ways? What do we do now in measuring energy by our meters? Do we not conduct an operation which for indirectness is comparable with the following hypothetical but possible method of measuring a distance? Suppose that, instead of straightforwardly applying a measuring scale to determine the distance between A in London and B in Edinburgh, for example, we traversed the distance in a vehicle, the while making determinations of its velocity as it varied from time to time, and of the duration of the journey; and that we then performed a complicated integration of velocity/time, and in that way ascertained the length of the journey. That would be measuring a scalar quantity, distance, by determining derived quantities—rates of motion—and integrating with respect to time; exactly, in principle, what practically all electricity meters do. Can no way be found of substituting a direct form of attack for this indirect one?

Nearly all the outward manifestations of electronic activity—electrostatic, thermal, chemical, magnetic—have been laid under contribution for effecting electrical measurements. The magnetic manifestation is the one now almost exclusively used for energy measurements. Is it beyond all bounds of possibility to utilize new combinations of these, or even hitherto neglected ones such, for example, as gaseous conduction or radiation phenomena? I must, I fear, leave this in the form of an interrogation. But the posing of the difficulty may perchance stimulate some of the younger generation to apply themselves to seeking a solution, by casting aside all preconceived ideas which have for the last 40 years accumulated round the subject.

Even with our present methods, another way of escape from our accuracy difficulty seems open, or at least not definitely closed. In measuring electrical energy we do not, indeed dare not, allow our instruments to absorb the energy that is measured, in the way that some forms of mechanical absorption dynamometers do. The flying electrons are caught in our instruments, made to give an account of themselves, and then allowed to pass on to their proper business of lighting our lamps or turning our motors, etc. Of course, they do not get through that ordeal quite scot-free; they have to do a little work. Not much, it is true—they have to turn a disc against a little magnetic friction, and turn the wheels of a counting train. The actual mechanical work is absurdly small; so is the levy demanded for this purpose from the electron flow—that is, small in comparison with the amount actually measured. But the disproportion between these two small amounts, i.e. between the electrical input to, and the mechanical output from, the meter is simply amazing; it is something of the order of 50 000 to 1. This fact has never ceased to strike me with astonishment. Why cannot a meter, considered as a motor, converting electrical energy into mechanical energy, be more efficient than that? Of course, it is admittedly a very small motor and, as we know, small motors are in general less efficient than large motors. A kind of anti-relativity principle reigns in this domain. In respect of some concrete things there is a sense at least in which we can say that smallness and largeness are not purely relative. Indeed, I believe that even in these days it is not orthodox to say that *all* things are relative. There are absolute things, but they have to be sought deeply for. Apart from abstract ideas, however, it is not necessary to look far for certain kinds of absolute magnitudes. For example, aggregations of matter in the form of planets, under a certain size, cannot retain atmospheres. Larger aggregations, like the luminous stars, have an upper limit of size and are observed to be nearly all of about the same mass, owing to the gravitational concentration of nebulous matter which forms them being ultimately limited in amount by the disruptive tendency of the enormous internal torrent of radiation. Small communities could not easily sustain insurance schemes; there are too few to share the risk. Engineering appliances, like motors, transformers, engines, etc., have a limit of size—not well defined, it is true—below which it is hopeless to expect any approach to ideal 100 per cent efficiency. But it is a dismal thought that a meter can never be expected to have, as a motor, a better ratio of input to output than 50 000 to 1. It may be asked, " Why trouble? " Well, presumably a meter having higher mechanical working forces than at present would much better perform its functions as a meter, and our accuracy difficulties would tend to disappear in consequence. A curious consideration, however, emerges here. In presence of the eternal urge towards cheapness, manufacturers dare not make their meters much more efficient, in the sense I have just used the word, for the reason that higher efficiency means higher driving torque for the same watt loss; and higher torque necessitates stronger permanent magnets to damp down the disc movement. So that even a modest four-fold increase of efficiency would involve a positively prohibitive cost for the necessary permanent magnets. This is, indeed, not a fanciful notion. Manufacturers cannot afford to make ordinary meters, at prevailing prices, with torques much higher than they are now. May I suggest this as the reason why meters are not made far more accurate than they actually are?

But it is legitimate to ask whether we really want more accurate meters. It would take a very bold man to answer that question in the direct negative. And yet an unqualified affirmative might not altogether be justified. In this connection I would refer to a statement made by Mr. C. G. Morley New, in his address in 1927 as chairman of the Western Centre.* There is much food for thought in that passage.

I conceive the real function of supply meters to be to provide equitable and determinate means, rather than any arbitrary means (leading to approximations only), of fixing the relative amounts of individual consumers' contributions. But it is to be observed that, under the guise of two-part tariffs, arbitrary means are becoming more and more prevalent as part at least of the modern systems of charging. It is now common practice to charge the consumer that part of the cost of supply included under the heading of "fixed charges" upon the basis of an assessment, either on aggregate connected load, or rateable value of premises, or floor space, or something similar. Such charges by assessment cannot, at least at present, be adopted to the exclusion of all other factors, mainly for two reasons, viz. the risk of waste by negligent consumers, and the wide diversity of the capacities for consumption of energy of different consumers, ranging from small domestic demands of a fraction of a kilowatt to large industrial demands of hundreds or thousands of kilowatts. The latter class obviously, for equity's sake, exacts a tariff based on accurately ascertained facts and costs, and this involves among other things, as a *sine qua non*, extremely accurate metering. This raises a consideration of some importance. As regards both price and watt loss, manufacturers have, figuratively, in recent years been driven down a kind of asymptotic curve. Even this statement may be too sanguine, since an asymptote implies a limiting value, and I am not sure that there is yet one in sight for this process, except it be zero. However admirable this tendency may be from the user's standpoint, and admirable as it may be for its disciplinary effect upon the manufacturer in imposing upon him in respect of cost, increased efficiency of production, and in respect of low losses, increased economy in the use of material, it is a tendency, in my opinion, containing elements of danger, one reason, among others, being that it is an undiscriminating tendency embracing in its field all kinds of meters, large and small. I consider that a broad distinction should be drawn between small meters for which low prices and low losses are admittedly important features, and large meters for which these features sink into relative insignificance. The manufacturer should surely be allowed a little more margin, economic and technical, to enable him to supply a better, more accurate, meter, for really important supplies. Especially important is this consideration when we remember that so many large meters have demand indicator attachments upon the readings of which the transfer of large amounts of money depends. The mention of demand indicators leads me to remark how curious it is that the exigencies of the conditions governing electrical generation and supply, combined with the efforts of the tariff builders, have imposed upon engineers the necessity of providing for the automatic measurement of a quantity based upon so artificial a conception as that of average maximum demand. It is a conception which involves a necessity unparalleled in any system of measurement, other than electrical, of which I am aware. It seems to be the exclusive privilege of electrical engineers to have to determine that particular value of unvarying rate of flow of energy, through a meter, which in a given time interval would have produced, had it been flowing, exactly the same number of integrated units as was really produced by the actual experienced load, however fluctuating. Many problems, mainly of a mechanical nature, have presented themselves for solution in connection with maximum-demand measurement, and most of them are now satisfactorily solved. One problem, however, still remains unsolved, if we are content to allow the exception of thermal types of demand indicator. I refer to the fact that time switches, or equivalent apparatus, pick out successive time intervals for resetting demand-indicator mechanisms at arbitrarily allotted epochs, which may split the peak of the load curve instead of completely straddling it, in which eventuality the ideal maximum load period is not exactly accounted for. We still await a tripping apparatus endowed with prescience, capable of holding its hand as it were, and being ready to start a resetting period just when it can foresee the immediate incidence of a period which is going to embrace the true maximum load.

As though the artificiality of the maximum-demand conception were not enough, we have, superimposed upon it, the even more transcendental idea of kVA, and the problem of its measurement. On this particular subject I desire at the moment to do little more than pay a tribute to the work of those whose labours have crystallized out into some really beautiful examples of inventive skill designed for kVA measurement. We may, I think, legitimately feel proud of the capacity of meter engineers for tackling and solving any problems, be they never so perplexing, and for exhibiting inventive genius second to none.

The subject of kVA and its collateral, power factor, have raised problems not only of achievement but of exposition. The difficulty of explaining to non-technical people the nature of these quantities has stimulated many to offer from time to time very clever and illuminating analogies drawn from interests in life other than electrical, in order to expose what really underlies the ideas expressed by kVA and power factor. Useful as such analogies may be, yet direct technical explanations are preferable for technical people, and of such explanations those of a graphic character generally convey the underlying ideas more clearly than any other. I have here a very beautiful graphic model, devised by Mr. Dance of Birkenhead, whose kindness in allowing me to use it here I very gratefully acknowledge. This model shows the outlines, or silhouettes, of a.c. voltage, current, and resultant power curves; and also a related crank diagram. A complete sequence of relationships between the three elements, and the phase displacement of the two vectors, can be exhibited. It shows clearly how, at power factors other than unity, some of the energy is wastefully flung to and fro like a shuttlecock.

---

* *Journal I.E.E.*, 1928, vol. 66, p. 27, col. 2, 1st complete paragraph.

It is quite unnecessary for me to dwell upon the theoretical aspect of this in this address. The importance of the theory, of course, is here quite subservient to the interest of the apparatus itself, which for demonstration purposes has great advantages over a set of laboriously prepared, and disconnected, diagrams on one hand, and on the other hand over the expensive and cumbersome cinematograph method, especially as the movement of this model can be arrested at any stage in order to allow any particularly interesting phase of the operation to be studied.

TABLE.

Progressive Reduction in Sizes and Weights of Induction Meters.

Approximate date	1890	1896	1905	1913	1929
Space occupied, cub. in.	900	300	165	135	75
Total weight, lb.	80	15·5	8	4·4	2·75
Weight of voltage element, lb. ..	14	3·7	1·2	0·7	0·44
Weight of current element, lb. ..	11·5	1·5	1·2	0·4	0·28
Weight of disc, oz.	2·1	4·7	1·1	0·9	0·8

Reverting to general aspects of the electricity supply meter business, the impressions derived from it by uninitiated observers might be quite deceptive. On the technical side, development may seem to flow in a very placid stream. Meters are now, it may seem, much as they ever were. Truly, there have apparently been no spectacular or revolutionary advances, as there have been in other branches (e.g. wireless). Yet there has been not only steady and definite progress on the technical side but enormous expansion in the way of new designs of meters for special purposes. As regards general development, one had only to glance back at the records of some 25 to 30 years to see, from the narrowest point of view, what phenomenal progress has been achieved. So we see the great advances that have been accomplished in economy of material and space (a condensed summary of which is given in the table above); in elegance of construction, and, hidden beneath and underlying all, great progress in subtleties of design.

As with the meters themselves, so with the outlook of meter engineers. Very different is it now from the days when the testing and maintenance of house service meters were their sole concerns; and, not less important, even their material prospects have improved. But of course, as a concomitant, and as a contrast too, the meter engineer has now, if he would be a man of really complete parts, to be equipped with a most comprehensive range of knowledge—he should know a great deal about mathematics, even about elliptic functions, for example, if he would understand all the profundities of the Aron meter theory; quaternions to enable him to perform vector analysis for the real understanding of the induction meter and other a.c. problems; chemistry to probe into the properties of the materials he uses and the peculiarities of such things as lubricating and insulating oils; metallurgy to understand his steels, permanent magnets and pivots; and general physics and electrotechnics to realize the full range of application of his meters to present and future problems. Above all, he should have a profound knowledge of mechanism, since in these days of prepayment meters and other complicated apparatus at least half his interests must be concentrated on mechanical and not electrical things. Whether or not such a paragon, completely fulfilling the above specification, could possibly exist I am not prepared to say. But all meter engineers, whatever their capacities, should rejoice that they live in an age when their problems are so much more interesting, even thrilling, than they used to be. Among others, still outstanding, there are the metering of super-tension supplies of 100 000 volts and over, avoiding the tremendous difficulties of potential transformers for such voltages; and the impending problem of metering high-tension d.c. supplies.

I have spoken a great deal about supply meters, but I have had no intention, of course, of identifying them as the sole items of interest under the heading of Meters and Instruments. Many other important things there are, e.g. transformers, relays, and general measuring instruments, which deserve the attention of our Section. For lack of time I must perforce leave them to other occasions. I have contented myself with a little discursive philosophizing on metering, pursued with some inside knowledge perhaps, but from a somewhat detached point of view. What lies in the future is no doubt a puzzling question. But as Sir Thomas Browne wrote long ago: " What song the Syrens sang, or what name Achilles assumed when he hid himself among women, although puzzling questions, are not beyond *all* conjecture." Neither is it beyond all conjecture what might be the outcome for the art of metering if electricity supply were to become so abundant that it could be charged for as water is now, without the use of meters; or if supply were to be distributed by some as yet unknown form of radiation through space, such as broadcasting. What would happen then? I can only echo the words put into the mouth of the Earl of Warwick by Shaw at the real point of termination of his play " St. Joan "— " I wonder."

WESTERN CENTRE: CHAIRMAN'S ADDRESS

By S. B. Haslam, Member.

(Abstract *of Address delivered at* Cardiff, *14th October*, 1929.)

The more recent Addresses submitted by the Chairmen of this Centre have dealt with the problems of the industry as raised by recent legislation, but it seems to me that the general trend of industry to groupings and amalgamations provides problems which are more vital and more deeply seated than any others. These problems affect the various branches of our industry in different ways. Those of the supply side have already been dealt with, and the work of the Central Electricity Board and the consequent establishment of what is known as the "grid" is a noteworthy example of grouping. What the result may be time alone will show, but nobody can deny that the scheme has received most efficient and loyal support even from those who were and are not in entire agreement, and while success will be assisted largely by the efforts of those concerned, failure, if any, can only be due to fundamental faults, not of design, but inherent to the general idea.

It may therefore be taken for granted that for the present the supply side of our industry, whether undertaken by municipal or private enterprise, is being tackled in a comprehensive manner; but otherwise the industry as a whole, and especially the manufacturing side, is seriously affected, and some drastic reorganizations will be necessary if we are to maintain our position compared with our foreign rivals.

It is with the economic aspect that I propose to deal, and to put before you some ideas regarding the commercial development of the industry as affected by conditions which have grown up since the War and are now in existence. Recent legislation has no doubt been adopted with the primary object of widening the use of electricity; and, assuming that this praiseworthy object is achieved, a greater demand for electrical products will be created in the home market, while foreign markets offer an ever-increasing field. It is difficult to decide as to the importance of the foreign market. Generally, it will be agreed that export business is not in itself remunerative to any manufacturer, but nevertheless it is of paramount importance in that the load factor of the factory can be considerably improved thereby with resulting benefits to the home market and to the manufacturer's own costs of production.

Figures taken over the last three years will show that in electrical plant the export business is divided almost equally between this country, the United States and Germany; but, unfortunately, whereas in 1926 our share was slightly greater than that of either of the others, the figures for 1928 show that both of our competitors have had a slightly larger share than we have. But if we take into account the Dominions and our Colonies, and remove from the total export figures the value of the electrical goods sent to other parts of the British Empire, it will be found that our share of the foreign trade compares very badly with those of our chief competitors.

In this connection an article recently published in the *Electrical Review* * is of interest. The article includes a table showing as percentages the world exports of electrical products, the figures for 1928 being as follows:—

Germany, 28·8 per cent.
United States, 24·0 per cent.
Great Britain, 20·2 per cent.

To students of the general industrial situation abroad as well as at home, the most noteworthy feature has been the wonderful revival of Germany in the past three or four years. The cause of that revival may be summed up in the one word "Rationalization." In this address I propose to submit my views on this subject, which may well be divided under three headings:—

(*a*) What is meant by rationalization?
(*b*) What results, if any, have been obtained by rationalization in productive industries generally?
(*c*) How can the knowledge gained in other industries be applied to our own? What results can be anticipated, and how can such results be used to the best advantage?

Dealing with the first point, the word itself has been described as "a new word, made in Germany, which stylists proclaim to be an abomination. Nobody has yet succeeded," the writer adds, "in saying shortly what it means, but that it means something of importance is not open to doubt."

There is no doubt that all industrial countries will be devoting much time and thought to rationalization during the next two or three years, and to enable the full significance of the word to be appreciated it is necessary that the origin and evolution of the process be clearly understood.

Many statements on the subject have been made and many definitions have been attempted, and it must be emphasized that no definitions made by people with any knowledge of the subject contain any suggestions that the maintenance of prices or the elimination of competition is part of the scheme.

The careful and comprehensive definition published by the World Economic Conference held in May 1927 may be taken as covering the subject as well as is possible in a few words. This definition is as follows: Rationalization is understood as "the methods of technique and organization designed to secure the minimum waste of either effort or material." It includes the scientific organization of labour, " standardization both of material and products, simplification of processes and improvements in the system of transport and marketing."

---

* "The World's Electrical Exports," *Electrical Review*, 1929, vol. 105, p. 515.

Dealing with the results obtained by rationalization, it may generally be stated that the lead in this matter was taken by the Germans, not, as the many admirers of that country would have us believe, owing to superhuman foresight, collective daring and energy, but because financial conditions forced its development in that country before the necessity became so overwhelming in this country. In both countries every kind of scheme—financial amalgamation, central selling, market control, output regulation, and all the other shifts known to capital—have been taken up as the exigencies of the moment seemed to demand; and the demand in Germany may be said to have occurred at 5 minutes to 12, whereas ours became imperative at 5 minutes past 12.

The year 1924 may be taken as the year when general and financial conditions in Germany were at their worst, and, while it was in this year that rationalization was seriously considered and schemes were first put into operation, it was not until the following year that these ideas became generally adopted in all of Germany's main industries; and a brief comparison between the latest available figures for 1924 and 1928 will be interesting and illuminating.

In the coal industry the output per man per shift, including all workers above and below ground, increased by 38 per cent, i.e. from 16·8 cwt. to 23·2 cwt. During this time the actual output increased by more than 15 million tons, and the exports, excluding reparation deliveries, increased by 22 million tons.

During this period the average earnings per shift of the underground worker increased from 6s. 2½d. to 9s. 5½d. and of all workers from 5s. 5½d. to 8s. 2½d. General conditions of living also improved, and during 1927, with the cost of living about 50 per cent above the figure for 1913, the average earnings amounted to 53 per cent above pre-war level. At the same time it will be realized that their recovery did not come about without hardship, and the unemployment figures show how the first steps of rationalization cause unemployment owing to the necessary reductions of surplus workers; but also how, ultimately, these unemployed can be, and are, absorbed in other work which naturally follows in the wake of successful basic undertakings. The figures for the mining industry are as follows:—

In 1924 the total number of workers employed was 463 000. As the measures for the concentration of production, by the closing of inefficient or costly mines and seams, were put into operation there was a steady decline to 396 000 in December 1925, and to 355 000 in May 1926. In March 1927 the number of workers had risen to 418 000, leaving only some 45 000 unemployed; and more recent figures as regards total unemployment show that these have now been absorbed in other work.

The process of rationalization was also adopted in the iron and steel works. Of necessity this process is more complicated and full benefits have yet to be obtained, though remarkable progress has been made and notable results achieved. Production has increased, from 1924 to 1928, by 5 300 000 tons, or 68 per cent, in the case of pig iron, and by 6 500 000 tons, or 65 per cent, in the case of steel. As regards the workers employed final figures are not available, but at least 30 000 more workers were employed during 1928 than during 1924, so that the industry not only re-absorbed the surplus workers dismissed when the schemes were first put into operation, but also absorbed a considerable number who were redundant in some other industry. During this period, owing to improved methods, the daily output of steel per worker increased by 36 per cent. The financial aspect proved equally satisfactory, and the first full year's balance sheet of the main operating trust revealed a gross surplus of £14 000 000.

It must not be imagined that the burden of taxation, etc., is unduly light, as during the year in question the amounts paid for taxes were £3 000 000 and for social services £2 500 000. Wages did not rise to the same extent as in the coal mines, the average increase being 26 per cent. The question of hours worked is of interest, and many employers will maintain that in this lies the whole secret of the trade revival. The normal working week is from 48 to 54 hours, though the tendency is to reduce this and 46 per cent of the workers now work the 48-hour week as against 26 per cent in 1924.

Similar results attended rationalization in other directions, notably the electrical, chemical, artificial silk and textile industries, but the examples quoted may be taken as average and in no way showing inflated results. Any estimate of the general results of German rationalization must be tentative. It cannot be suggested that the state of the country is normal, but it cannot be denied that conditions show a very real and definite improvement as compared with those of 4 years ago. So marked is this improvement that it is worth while to attempt a tentative survey.

In 1924 wages were extremely low, and a 12-hour working day was not uncommon. Such conditions favoured communistic propaganda, and it is needless to say that very energetic efforts were made to exploit the sullen anger of the workmen, while at the same time the movement to establish the currency and re-establish the gold mark was sending prices bounding upwards. Gradually wages became adjusted to the rising prices, and though there was little unemployment the rate of individual productivity was low. This low output caused high costs of production and, coupled with short time, working costs rose to an impossible figure. The banks were charging 12 and even 14 per cent for loans, and credit was thus restricted to very narrow limits.

This, briefly, was the condition of German industry, and the only apparent alternative to collapse was rationalization.

The first outstanding result of putting rationalization into effect was a rapid increase in unemployment. In September 1925 the number " on the dole " was about 250 000; by the end of the year it was over a million, and by the end of February 1926 it had reached the 2-million mark.

Subject to comparatively small seasonal fluctuations, this figure has steadily decreased from that time, and in October 1927 it had fallen to under 400 000; and though the number of unemployed to-day is greater than this there is still a very substantial reduction. The main features of this recovery may be summarized as follows:—

(*a*) The rise in individual output following the closing of the less efficient mines and works, the concentration of full-time production in those best adapted for preservation and extension, and rapid progress in modernization of plant.

(*b*) The steady improvement in the physique and morale of the workers due to the rise in wages and standard of living.

(*c*) The elimination of duplicated activities and other forms of waste of labour and plant.

(*d*) The immense reduction in transport costs, due to the allocation of production to particular works for particular purposes and centralized control of the movement of raw materials and finished goods.

(*e*) The advance in full utilization and progress in general technical and scientific practice and further concentration of sales organizations.

While it is not possible at this period definitely to say that the improvements in the German industrial conditions are permanent, there is very substantial evidence that these improvements are founded on solid ground, and we may ask ourselves how the experience gained may be adapted to our own conditions.

Since this address was written, a White Paper has been published by the Department of Overseas Trade, dealing with the financial and economic conditions in Germany during the period 1928–9. This report shows very clearly that the prosperity of that country is general and continuing; rationalization is progressing rapidly, especially in the coal and coke trades.

During the period under review industrial activity has been slowed down considerably, owing partly to the loss of production attendant on re-equipment of works and rationalization, and partly to financial causes, such as the American demand for money and the high rates of bank interest. Yet, notwithstanding this, the savings of the German people continue to show an upward movement. The deposits with German savings banks at the end of 1928 amounted to £454 000 000. The increase during 1928 amounted to about £135 000 000. While the British iron and steel industries are labouring in deep water, the report tells us that, on the whole, the German iron and steel industries may be said to have overcome successfully a critical period.

German shipyards were better employed during this period; the engineering industry had a better year than in 1927.

German foreign trade showed "the remarkable increase of £70 860 000" in exports for 1928; this compares with a British increase of only £14 000 000 in the same year.

"The strain to which German economic life has been subjected during the first five months of 1929," states the report, "serves to emphasize the fundamental stability and soundness which it has developed since 1924."

Quoting once again the article in the *Electrical Review* previously referred to, "the greatest support of the English industry is stated by the report to be found in the Dominions and Colonies, which take about two-thirds of the total exports. For the rest the British exports are said to have made no progress since 1925, and from 1926 have even fallen as a percentage of the world total. At the same time German imports into Great Britain have increased from 104 million marks in 1925 to 126 million in 1928, or over one-third of the exports, the reason cited being declining competitive capacity owing to the lack of rationalization."

It must be realized that fundamentally the Englishman is not temperamentally suited to the conditions of rationalization: he is by nature and upbringing an individualist. It is very doubtful whether any country is psychologically so well fitted to the system as Germany. This is a definite weakness requiring careful consideration when applying these modern industrial conditions in this country, and many people will maintain that conditions which may change the general character of our race cannot possibly cause any permanent improvement. Undoubtedly the age of amalgamation and specialization is upon us. The result of amalgamation among our large industrial concerns, and the formation of combines each with one huge head office and one centralized organization, is to create a general tendency to split up the organizations into sub-divisions, each dealing with a particular portion of the industry.

The effect of this is "mechanization," and the human element becomes reduced to a minimum. The old order with the capable all-round business man taking charge of the whole business is rapidly giving place to the new, and the young departmental head specializing in his own particular branch is coming to the fore. Unfortunately, too often he has not the advantage of a general all-round training, and therein weakness lies. It is fairly easy to obtain and train a routine worker for one or two of the various departments in an industry, but it becomes increasingly difficult to find the all-round expert for the control of all departments.

Economists will maintain that prosperity in the future will depend on standardization and specialization of both industry and labour. Both undoubtedly tend towards the cheapening of a commodity and a higher efficiency in organization, but they also lead to a much larger number of purely routine workers and a shortage of all-round experienced leaders. Standardization and specialization must come, but the ultimate measure of success will depend largely upon whether this weakness of modern organization can be overcome; otherwise our industries will in the future be dependent on an army of specialists who will know very little themselves of the actual internal organizations of their own concern.

The system which has proved so successful in Germany is being put into practice in this country in most of our industries. The chemical combine is perhaps the most noteworthy example, but other industries are adopting the same principles in varying degree. Time alone can show what the results will be, but it is to be hoped that those who control and direct the combines will realize that the object to be aimed at is economy and, therefore, lower prices coupled with higher wages and better working conditions.

Undoubtedly, one of the immediate and most important questions which will arise will be that of finding, or rather recovering, the markets for our goods. If rationalization, complete or in a modified form, when put into operation in this country produces results similar to those obtained in Germany, increased production will result. This country cannot absorb such an increase and, therefore, markets in the Dominions and Colonies and abroad must be found and, when found, retained. Political activities will undoubtedly have considerable bearing on this problem, but when all is said and done the two chief factors will be the salesman and the publicity man.

Twelve months ago Sir Malcolm Robertson, British Ambassador to Argentina, said that we must look to salesmanship for the spread of British trade abroad, and for the recovery of our old position in the world's markets.

Again, in February, the Prince of Wales, speaking at the dinner held in connection with the British Industries Fair, stated that given the necessary modern equipment and methods the British workman could hold his own with anybody in the world. He went on to ask whether the salesmanship of this country was up to the standard of the workmanship of the men. It appeared to him that there must be something utterly wrong if a British community abroad anxious to buy British goods were unable to do so.

It is my very definite opinion that it is to the salesman that our industries must look if our old-time preeminence in engineering development is to be recovered. In making this statement I want it to be clearly understood that I am referring chiefly to the foreign markets, which as I have previously stated become more and more of vital importance.

It is an exploded doctrine that orders will come to the manufacturer; the man sent out to get these orders must be carefully selected. He must be a skilled trained engineer with a good and definite personality. He must be able to examine and advise on the work to be done; to calculate and guarantee the time of performance; to set up and start the plant when delivered, and finally, by actual demonstration, if necessary, to prove that his statements and advice were correct. In other words, only the best trained and equipped men should be selected.

There is in this country a very false idea that there is something undignified in the selling of specialized products, but I hope and believe that this idea is slowly and surely becoming eradicated, and that the younger generation will realize the importance of this branch. No matter how good may be the manufacturer and his products or how efficient the user, connection must be established, and I would suggest to all senior engineers and executives that they can do this country a lasting service by encouraging the young salesman. Of course, the manufacturers must do their part and send out only those men who know their job and who will not waste valuable time. When, in addition to the qualifications above mentioned, it is realized that for foreign business the salesman, or, as I prefer to call him, the commercial engineer, must know at least two foreign languages and speak and write them fluently, and must also study the manners and customs of the country in which he operates, it will be realized that his is no easy task and, therefore, is all the more worthy of encouragement. Sir Edward Crowe, Controller-General of the Department of Overseas Trade, at the last British Industries Fair emphasized how necessary it is to know various points of etiquette in foreign countries. In some you are considered an uneducated boor if you make a call in an overcoat; in others you must put on a glove to shake hands; in China the number 250 is never used if it can be avoided, and one firm making a 250-cm^3 motor cycle increased their sales enormously by calling it a 249-cm^3 model.

The subject of salesmanship is much too large to be more than touched on in this address, but I have indicated some of the lines on which the choice and training of the commercial engineer should proceed. To these must be added the quality or virtue of tact. Buyers and users of plant have their own prejudices and ideas, and these must be met and overcome without losing the confidence and goodwill of the buyer in question.

Lastly, the commercial engineer must be able to express himself well on paper. He must remember that the manufacturers thousands of miles away can only act on his reports, and he must put himself in the place of the man at the works reading these reports and enable him to grasp what is wanted in the way of design and estimate. On the other hand the manufacturer must place implicit confidence in these reports, and must remember that the man on the spot knows the local conditions, and should these conditions call for re-design he must be prepared to re-design if he wants his share of this business.

And now we come to the problem of advertising. Of late years advertising has become a profession in itself and the sums spent yearly on advertisement are enormous. Whether they are justifiable or not is a moot point. In my opinion, one of the benefits to be derived from amalgamations will be the restriction of these advertisements, and the sums thus saved will prove of inestimable value, whether put back into the industry for research and development, or given to the public by way of reduced prices. Of course, these remarks do not apply when dealing with foreign trade, as in that case foreign competition has to be met. For the home markets the propaganda work carried out by the British Electrical Development Association can be relied upon to do what is necessary to increase the number of users of electricity, and it is my serious suggestion that greater support of this Association by manufacturers and supply authorities will give good results, and at the same time materially reduce the individual advertising allocations of the subscribers. As regards foreign trade, different conditions have to be met and very special efforts made to keep British goods before the buyers.

Much could be written on this subject, which is worth very careful consideration. Many firms go to endless trouble to see that all wastage in production is eliminated, and yet place unlimited trust and large sums of money in the hands of an advertising firm without giving sufficient thought to whether the programme is likely to be remunerative.

It may be pointed out that this address, though delivered before a body of electrical engineers, does not deal specifically with that industry; but I submit that as far as South Wales is concerned, and to a slightly smaller degree the whole country, the electrical industry is dependent on our basic industries of coal, iron and steel and that, therefore, any remarks concerning the one will also apply to the other.

To sum up in a few words the commercial future of our industry as I see it, reorganization on rational lines is necessary, not only on the production but on the distributing and operating sides. Old-fashioned methods must go, and a new vision must materialize. Wherever possible, co-operative production must be put into operation and weak links cut out or strengthened, as costs can and will be reduced thereby.

There will always be the danger of amalgamations genuinely formed for better and cheaper production becoming debased into price-maintenance cartels, and this danger must not be overlooked. Trusts and monopolies have never yet benefited mankind, and it is to be hoped that our profession—the one above all others operating for the general good—may never be free from honest competition.

Another danger lies in the suppression of individual thought and effort. Those in authority must guard against this, as it is just that individual touch which distinguishes British goods all over the world.

The standard of commercial engineering must be raised and recognized, and both manufacturers and users must realize that it is only by co-operation that the industry can survive the great trade struggle between this country and its foreign rivals which is now commencing. The next few years will witness competition from abroad the like of which has never yet been seen. We need not fear this competition as regards quality: there are no goods to equal ours. We can meet this competition in price if only we realize what we have to do and set about it. We can regain the markets of the world if we abandon our somewhat insular methods and appreciate that the man who pays the piper has a right to call the tune. Let us therefore realize that in our industry each has a job to do—a niche to fill—and that each can help, not only the industry, but his fellow man if we will forget self and, with larger vision, regard himself as a small unit of the greatest industrial profession the world has ever known.

SOUTH MIDLAND CENTRE: CHAIRMAN'S ADDRESS

By G. R. J. PARKINSON, Member.

"ELECTRIC POWER SUPPLY."

(*Address delivered at* BIRMINGHAM, 16*th October*, 1929.)

During the last 45 years the advance in electrical knowledge and the application of electricity to so many purposes have resulted in engineers being compelled to specialize in some particular branch, and the concentration of their studies and research in that particular direction has necessarily left them with an indifferent knowledge of the intricacies of other equally important branches of their profession. Now this Institution caters for every class of electrical engineer, but as the whole of my experience has been gained in the electric supply industry I trust that those members who have followed other branches of our profession will forgive me if I confine my remarks to the only section on which I can speak with any authority.

The public supply of electricity was commenced about 1880. In 1882 the first Electric Lighting Act was passed, and, as the name of the Act implies, little importance was attached to the possibility of supplying electricity for any other purpose than illumination. At this time the financial return from electricity supply was of a very speculative character, and consequently the pioneer work of developing the electricity supply service was left solely in the hands of private companies, although provision was made in the Act that where a company was authorized to supply electricity, the local authority in whose area the supply was authorized had the right to buy out the company at the end of 21 years. This period was far too short: Electric supply was in its infancy, and progress was very slow until 1888, when a new Act was passed, amending the tenure of private companies by increasing to 42 years the period after which local authorities could purchase.

From this time onwards progress was more rapid. Many new companies were formed and, confidence in the industry being established, most of our cities and large towns applied for Provisional Orders under municipal control and, with the exception of London, the company undertakings were confined to the smaller towns. In all cases, however, the authorities for the individual towns were quite independent, and were only authorized to give a supply within the boundaries of their respective city, town or urban district.

Even at that date it was recognized that many of the supply areas were much too small to be operated on the most economical lines, and about 1898 a number of companies were formed, with statutory powers, to supply electricity throughout the comparatively large areas of one, two or three counties. These companies were mainly confined to supplying power to factories, and bulk supply to smaller authorized distributors, and were prohibited from supplying lighting except under separate Provisional Orders, and not in competition with existing authorized distributors. This latter provision stultified one of the main objects of the power companies, as it still left the country saddled with a large number of small isolated supply undertakings with small and inefficient generating stations. The 1919 Act was passed with the object of removing this disadvantage. The country was provisionally divided into about 20 Electricity Districts, and it was anticipated that a Joint Electricity Authority would be formed in each district, to consolidate under one ownership and one management the generation of electricity for the whole of the district. The Act also provided for the setting up of a Board of Electricity Commissioners who, in addition to taking over the duties previously carried out by a department of the Board of Trade, should be responsible for co-ordinating and judicially supervising the development of the electric supply industry. Unfortunately this Act, with the further provision of the 1922 Act, did not fulfil the expectations of its sponsors, primarily because the districts were not compelled to form Joint Electricity Authorities, and in 1926 a new Act was passed, still with the object of improving the methods of generation, by concentrating and interlinking, and thus providing a cheap and abundant supply throughout the country but on entirely new principles. Under this Act a further Board was set up, known as the Central Electricity Board, an executive body which was made responsible for co-ordinating the generation and main transmission of electricity throughout the whole country, without actually owning the generating stations. The Board will select a number of the largest and most economical stations and link these together by means of 132 000-volt transmission lines, thus forming a system of national busbars serving the whole country. The selected stations will be operated to the instructions of the Central Board, in such a manner as to generate the full requirements of the country at the highest possible efficiency, and considerable savings can be made by closing down hundreds of small inefficient stations, by running the most efficient stations at high load factor and utilizing the less efficient stations for peak loads only.

As previously mentioned, the first supplies of electricity were used almost exclusively for lighting purposes. The generators were rope-driven sets, with reciprocating steam engines as the prime movers. When I went to Portsmouth in 1894 the generating station had just been opened, and was considered one of the most up-to-date in the country. Electricity was generated at 2 000 volts by means of flywheel alternators and horizontal Corliss-valve engines. The alternators were of 212 kW capacity each, and we also had a small Parsons turbo-alternator of 75 kW. At that time records and performance tests were of the crudest, and integrating watt-hour meters were of doubtful accuracy, but from some of my old notes I find that the actual consumption was about 12 lb. of slack per unit sold. I have no record of the annual load factor, but it was probably about 8 per cent.

At this time, although most engineers realized that high load factor was the key to low cost per unit, very few had the courage to offer electricity at a sufficiently low figure to induce manufacturers to adopt electric driving in their factories; moreover, electric motors, especially alternating-current motors, left much room for improvement. It was not until 1898 that the idea of using electricity for industrial power purposes became popular. By this time considerable improvements had been made in induction motors, and experiments on the Continent had proved the advantages of polyphase transmission and distribution, but although a number of power companies started operations about this date it was some years before electricity was adopted to any extent for factory driving. It was extremely difficult to convince manufacturers that electricity could compete in cost with either steam or gas. Take this district, for instance: a fair quality of engine slack could be purchased at about 4s. per ton, delivered in barges alongside the works. Stokers' and engine-drivers' wages were about 5d. an hour for a 60-hour week, and, notwithstanding the many advantages of electric driving compared with steam, it was difficult to show an actual saving in cost and it was necessary to offer electricity at a very low rate in order to displace an existing engine. Nevertheless, electricity gradually won its way. By 1914 electricity was slowly but surely replacing all other forms of power in existing factories, and was installed almost as a matter of course in new works. During the War the demand for elecricity for driving machinery, electro-metallurgy and electro-chemistry was far beyond the capacity of the existing supply undertakings, and during the 5 war years it was impossible to install generating plant at a sufficiently rapid rate to meet the demand. We all suffered from the slump in 1921 after the feverish excitement of over-production and false prosperity in 1919-20, but since then electric supply undertakings throughout the country have experienced a steady and ever-increasing demand.

I have sketched very briefly the history of the electric supply industry in order to give an idea of the progress that has been made and the importance of the business, and I shall now refer to its bearing on our national economy.

Our very existence as a nation depends upon our ability to export manufactures in competition with the rest of the world. Not only must our manufactures be of such quality and kind as to satisfy our clients, but they must be offered at a competitive price. We are handicapped by heavy rates and taxes; the hours of work and rates of wages paid to our workpeople are in many cases higher than those of other competing nations, and our only chance of keeping abreast of our competitors is by reducing the cost of production. The question of rates and taxes we must leave to our politicians. Reduction of wages is out of the question, for the present wages are barely sufficient to maintain a reasonable standard of living. We must therefore look to the improvement of methods and the reduction of the cost of the utilities, the most important of these being heat, light and power. These have to be derived from some natural source. In many countries an inexhaustible supply is available from the rivers and can be obtained without draining the potential capital resources of the country. Unfortunately, we have only a very limited amount of water power available in this country, and until a commercial proposition for the utilization of the tides is available we have to depend almost entirely upon coal. In this respect we are blessed with very extensive coal deposits, and it is to this source that we must look for our supplies of heat, light and power. It should be remembered, however, that the supplies are not inexhaustible. We are, to an extent, living on our capital, and it is our duty to posterity to see that we utilize our national resources with reasonable economy.

Starting, then, with coal as our source, we have to provide the three utilities heat, light and power—utilities which are required by every member of the population, in the cottage, the mansion, the shop and the factory, and electricity is the ideal medium for obtaining these utilities from the raw coal and conveying them to the individual consumer. I shall refer later to other methods of domestic heating, but whether this is done entirely by electricity, or partly by other means, I feel that electric supply undertakings should be in a position to meet all requirements for heat, light and power.

Now as to the development of public electric supply. Referring to the Board of Trade Reports on the census of production, it will be found that in 1924 roughly 50 per cent of the power required in factories was obtained from electricity, and of this one-half was purchased from public supply authorities, and one-half generated privately, so that only one-quarter of the power requirements was met by public supply authorities, and we can look for a potential demand, for this purpose alone, four times as great as the output in 1924, independent of extensions and new developments. Railway electrification is another potential demand: whether or not our main lines are electrified, there is no doubt that we shall have large extensions in suburban line electrification. Then again, in electro-chemistry and electro-metallurgy we may look for considerable development. It is possible at the present time to convert iron ore into steel in an electric furnace, and although the process is not a commercial success at the moment it is not improbable that an improved furnace, working on a continuous cycle, and obtaining a supply at high load factor from a modern selected station, may be able to compete successfully with the blast furnace and convertor.

Lastly, there is the domestic consumer (and with the domestic consumer I include shops and offices) with a demand for heat, light and power equal to one-third of the requirements of the country for all purposes. Domestic electrification is a somewhat contentious question, even among electrical engineers. I am not convinced that the all-electric house is the ideal, from a national economy point of view. I would divide domestic electrification into two sections:—

(1) Including lighting, occasional heating, cooking, ironing, washing, ventilating, vacuum-cleaning, refrigerating, etc.
(2) The general heating of houses, and hot-water supply.

In the first section electricity not only offers enormous advantages from the point of view of convenience, cleanliness, health and labour-saving, but it can be supplied at a cost which compares favourably with other methods. The second section is, however, in a different category. Under the best conditions the thermal efficiency in the production of electricity is only about 18 per cent when reckoned at the consumer's terminals. Coke and coalite can be burnt in a closed stove, for heating the house and the hot water, at a thermal efficiency of at least 50 per cent; moreover, general heating is required for only 5 or six months out of the 12, and the universal adoption of electricity for general heating would have a serious effect on the load factor of our generating stations and prevent that reduction in cost which we are all anticipating as the demand for electricity extends. On the other hand, if electricity were confined to the first section the occasional heating in the summer months, when general heating is not in use, would tend to equalize the summer and winter demands and thus improve the load factor. I am, of course, speaking in general terms: there are no doubt many instances where both general heating and water heating, particularly if combined with thermal storage, can be, and have been, installed with most satisfactory results.

I have referred to the fact that in 1894 it was not uncommon for a generating station to burn 10 to 12 lb. of coal per unit sold, or, say, 8 to 10 lb. per unit generated. Since that date, engineers have so improved the design and operation of generating stations that, together with the larger demand and improved load factor, in the most up-to-date stations it is possible to reduce the consumption to less than 1½ lb. per unit generated. It does not appear probable that we shall be able to reduce this very much further without introducing such complications as would counterbalance the reduction, and I think we must look in the future for further economies by extracting and selling by-products. There are a number of processes now in use for the extraction of gas, oil and tar from coal, and leaving a coke residue known as coalite, which makes an excellent smokeless fuel, and such a process can be conveniently combined with the generation of electricity. The low-temperature carbonization of coal is essentially a continuous process, and a supply undertaking could run such a process at 100 per cent load factor, burning the whole output of gas and coalite on full load and storing the excess of coalite during light loads, the excess being sold to consumers for the general heating of their houses, just in the same way as the gas undertakings sell coke. The oil and tar recovered should more than repay the cost of carbonization. Naturally, the quality of coal available, whether suitable for carbonization or not, and the relative cost of other fuel available in the district, would require very careful consideration, but I feel that an electric supply undertaking should be in a position to meet all the requirements of the public in supplying heat, light and power, and a combined system of carbonization and electric generation offers an ideal method, both from a national and a personal economy point of view.

Few people realize the vast quantity of coal burnt in open grates. In 1927, 180 million tons of coal were consumed in this country, and of this total 40 million tons were used by domestic consumers. We, as electrical engineers, claim that not only is this coal used most uneconomically, but that most of our smoke, dirt and fog is due to the open grate. It is true that the general use of coalite would not dispose of the inefficiency of the open grate, although it would make a big improvement in the smoky atmosphere of our towns and cities; but the public should be educated to make more use of the closed stove, combined with central heating and hot-water supply. I was discussing this question recently with an engineer in Switzerland. Owing to the large amount of water power available in Switzerland, from a national economy point of view it would be to the advantage of the Swiss to use electricity for every purpose, but this engineer told me that, notwithstanding their intensive electrical developments, they could not supply electricity for general heating purposes at a price comparable with the cost of coal, and in most of their hotels and large buildings they used coal or coke for central heating, and electricity for lighting and all auxiliary purposes.

You have all heard of the experiments carried out by the Newcastle Electric Supply Co. for the carbonization of coal in connection with the generation of electricity. Their Chairman stated recently that their experimental plant had proved the commercial possibility of this combination, and I understand that they are now making considerable extensions to their carbonizing plant. At the present time there is keen competition between gas and electric supply undertakings, a competition which has been of undoubted advantage to the public and has led to most of the improvements in both electric and gas lighting. On the other hand, it is not economical to have two systems of distributing heat, light and power, involving double sets of distribution mains and services, and administrative charges, and, further, the healthy competition has often developed into rampant antagonism. It may be that some day we shall see the gas and electric supply undertakings working together—the gas department taking responsibility for the carbonization and leaving the electric department to generate and distribute electricity and coalite to meet all the requirements of the public for heat, light and power.

IRISH CENTRE (DUBLIN): CHAIRMAN'S ADDRESS

By T. J. MONAGHAN, B.Sc.(Eng.), Member.

"THE PROGRESS ACCOUNT."

(Address delivered at DUBLIN, *17th October,* 1929.)

The task I have set myself to-night is to examine a few of the current entries, debit and credit, in the ledger of progress.

First let us decide what we mean by the word "progress." If it were possible to obtain the considered views of the educated public as to the principal benefits conferred upon the world at large by the scientific advances of the past one hundred years, there can, I think, be little doubt that the consensus of opinion would be very much as follows:—

(1) Vastly improved methods in medicine and in surgery.
(2) Rapid transport by road, rail, sea and air.
(3) Enormously improved communications by the aid of telegraphy and telephony, including wireless.
(4) A general improvement in the standard of living.

Examining this agreed list, we find that almost all these developments are really concerned with loosening the fetters of space and time, that are, or rather that seem to be, imposed upon mankind in this material world.

The improvements in medical science have added something more than a decade to our expectation of life as compared with that of our grandfathers', and have, furthermore, by the potent aid of antiseptics and anæsthetics, substituted hours of mere discomfort for the days of agony endured by earlier generations of patients.

Modern transport enables man to spend most of his time where he wishes to be, rather than, as hitherto, in covering the space separating him from the place of his desires. Modern communications enable him to disregard to a very considerable extent the limitations of both space and time, and to exchange ideas easily and quickly with his brethren wherever they may be.

By the somewhat vague description "an improved standard of living" we mean such things as the release from drudgery in workshop and in home rendered possible by that most useful servant electricity, such things, too, as the health and comfort given by ventilation, refrigeration, heating, etc.—products of an electrical age.

Now all these tremendous advantages have increased very considerably the possible "efficiency of living," which expression I would define as the ratio of the time spent in doing the things we want to do, to the total time at our disposal. This higher efficiency of living has created for the world, in the aggregate, many years of that very precious commodity, time. These benefits have not, however, been won without toil and trouble, and in order to get some appreciation of what has been involved in reaching our present state of development, let us glance at its history.

The birth of each of the major advances in applied science has been due, I think, to inspired dreamers, practical visionaries, forward-looking men who were not satisfied with things as they found them and hence were always seeking to push on into the land of new ideas. It is such men as these who, in the lifetimes of many of us, were so foolish as to believe that aeroplanes and transatlantic telephony would one day be normal public facilities though the solid citizen knew such things to be but wild dreams and vain imaginings. Fortunately, such visionaries have usually been able to infect with their enthusiasm a few holders of the purse strings, but, unfortunately, it has usually happened that the scientist has lost his time and hope, and the capitalist his money, without reaching the goal of their desires.

But the way to progress has extorted a heavier toll than time, hope and money, for many of the seekers after knowledge have been willing to gamble with their lives. Doctors have allowed themselves to be inoculated with fevers and other dread diseases, in order that treatments and antidotes might be tested under carefully supervised conditions; the earlier workers with X-rays have continued to labour for the benefit of humanity while suffering the agonies of X-ray dermatitis, which has killed them at last; and in more mundane matters, such as the development of the motor-car and the aeroplane, there have been many venturesome spirits willing to stake their skill and luck against the forces of nature, in an effort to extend man's dominion. In the development stage, then, we find many instances of individuals who consciously staked their lives in an effort to prove a particular hypothesis, perhaps that a certain serum will cure a fever, perhaps that a certain car can travel at more than 300 miles per hour. Thus have the amenities of scientific progress been won for the benefit of the world at large, and we may well pause to pay our tribute of respectful gratitude to those who have struggled so hard and staked so much on our behalf.

The fruits of progress that we are considering have passed beyond the development stage, and through the next stages of experimental and of restricted private use, and are now available to, and utilized by, the general public on an ordinary commercial basis. Successful commercial enterprises have to be at least self-supporting, that is they must be offered to the public at a price that the public believes to be fair and reasonable for the services rendered and is therefore prepared to pay.

In talking of price we usually mean cost as expressed in terms of the cash or commodities that we exchange for the wanted article, but I desire to emphasize that in the real price of these modern amenities there is an element much more important than cash, namely, human life. I spoke a little earlier of the deliberate staking of life by individuals in their efforts to wrest her secrets from Nature, but here we are dealing with, not a voluntary, but an imposed risk, borne by the public at large. In a dim sort of way the public recognize that most practical advances of science are accompanied by an element of danger; thus high-speed travel introduces risks not present in low-speed locomotion, the danger of electric shock could not arise in an unelectrified community, and aeroplanes could not crash if they could not fly. The mass of mankind recognize and accept these risks, in a vague and uninformed way, but there is a limit to the risk that the public will take. For example there is, at the moment, a mass searching of heart going on throughout the world as to whether the toll of life and limb being exacted by motor-car accidents is not altogether too high, and the public are, I think, prepared to acquiesce in restrictions on their present degree of liberty in an effort to reduce the present very high accident rate.

We should really consider then, in each case, the two elements of cost—cash and risk—before deciding whether a thing is cheap or dear, and it often happens that the cash element can be reduced if one is prepared to increase the risk.

Turning now to the particular commodity in which we are all interested, namely, electricity, let us consider the risks, actual and relative, attendant upon its use. There have been many arguments upon such matters as wiring rules, standards of construction and so on, that I, for one, have found somewhat unreal, because of the difficulty of measuring the amount of protection gained or the extent of the risk run. In an effort to throw some light on the matter, I have collected from various official sources some authoritative figures to which we can, with, I believe, considerable advantage, devote some attention.

Table 1 gives for various countries and different years particulars of the number of deaths from various accidental causes. The figures are not so bewildering and disconnected as they may seem to be at first sight; they assume some sort of order after a little scrutiny.

Let us consider first the figures for England and Wales for 1924. The figure for fatal accidents per 100 000 of the population gives us some sort of idea of the general risk level in the community, for comparison with that in the same country year by year and with the corresponding figures for other countries.

It will be seen that falls account for more deaths than any other single cause, though the figures for motor vehicles approach them closely. Accidents on railways are about 25 per cent of the motor-vehicle rate. The figure for accidental absorption of poisonous or irrespirable gas is of interest for comparison with the electrical shock rates. The other figures I have selected, excessive heat and cold, lightning, cricket and football, give us some idea of the extent of little-appreciated risks.

A brief study of the table as a whole will show that there are no very large jumps in any of what we may call the man-made causes from year to year (excessive heat, which is outside human control, showing, I think, the widest variations). There is, however, evidence of marked trends even over the short series of years I have shown in the table.

The United States is apparently prepared to live more dangerously than Great Britain, the ratio for all accidents being about 2 to 1, but in the domain in which we are specially interested, viz. electric shock, the rate in the United States, as compared with that in this country, is about 10 to 1. The American rate for gas deaths, is considerably more than 10 times the English rate.

Canada comes intermediate between Great Britain and the United States for electrical accidents and gas accidents.

It will be noticed that there is a tendency for the accident rate in England and Wales to rise in the years under review, and a little inspection shows this to be due chiefly to motor accidents. In England and Wales in 1924 there were more falls than motor accidents, falls still lead, but by a lesser margin, in 1925, but in 1926 motor accidents exceed falls and continue to advance in 1927.

In the case of the United States figures we see that, for the years under review, motor accidents have been more numerous than falls and are becoming more numerous each year, and the rate of accidents per 100 000 of the population is considerably greater than in England. A very considerable number of accidents due to falls and to motor vehicles is evidenced for each country in the table for each year.

It will, I think, surprise most people to find that in England and Wales one is more likely to meet a sudden end by falling downstairs than in a railway accident; in the United States, however, the risk rates for these causes are reversed.

The number of deaths in England due to excessive heat came as a surprise to me, and it is interesting to note that the figures for this cause of death for England and Wales and the United States move in sympathy over the years shown. Thus, taking 1924 as a datum, there is a marked rise in both countries in 1925 and both show a fall in 1926. I expected, but did not find, some correlation between deaths due to lightning and those due to excessive heat.

These comparisons are, I think, all of interest, but their real value for our purpose to-night is to enable us to see in correct perspective the entry with which we are particularly concerned—deaths from accidental electric shocks.

Taking England and Wales first, for which my figures are most complete, it will be seen that the deaths due to falls out of bed are more numerous than those due to electric shock, and that, year in, year out, excessive heat and cold each levy a toll comparable with, and usually greater than, that levied by electric shock.

I would direct attention to the figures which show that accidents at football and cricket are responsible for about half as many deaths as electricity. Study of the table will suggest many other interesting comparisons that need not be detailed here.

Before we attempt to draw any rules for guidance from these figures, let us see whether we can analyse

TABLE 1.

	1924		1925			1926			1927	
	England and Wales	U.S.A.*	England and Wales	U.S.A.*	Canada (excluding Quebec)	England and Wales	U.S.A.*	Canada (including Quebec)	England and Wales	Holland

* England and Wales, 42; Scotland, 4. † England and Wales, 44; Scotland, 3.

them still further. It would be of considerable interest if we could separate the industrial accidents from the totals, but with the means and time at my disposal I have been able to do this only for Great Britain. The manner in which the various official statistics are published renders it easier to use figures for the whole of Britain for this purpose, rather than those for England and Wales alone as has been done in Table 1. In Table 2 is given, then, some analysis of the electrical accidents.

The percentage of industrial accidents is perhaps not so high as we should have expected. The information as to incidence by ages suggests some interesting reflections, and will be further invoked in evidence later on. It will be seen that quite young children figure in each country's return year by year. It has been suggested to me that possibly the uninformed use of electrically-operated toys has something to do with this, and personally I have a suspicion that unguarded wall plugs may also be a factor. The climbing age is in evidence, I think, in the 10–14 and probably in the 15–19 groups. The majority of the accidents occur to people in the prime of life, though the United States figures show that some quite elderly people are involved. The vast majority of the accidents occur to men.

An examination of these figures suggests the thought that the electrical accident rate in any country probably depends upon two main factors. The first is the general mental outlook of the people, i.e. the price they are prepared to pay for progress, or, in other words, the extent to which the conservative or the adventurous type predominates amongst the population, particularly in the ranks of those responsible for the compilation of electrical codes of rules. The second main cause that we should expect to influence the rate is the extent of user of electricity. Possibly, too, local climatic conditions may be of moment, but it is very difficult to get evidence of this.

Table 3 gives the consumption per head and the risk rates for various countries. This will repay examination.

TABLE 3.

Country	Accidental deaths from electric shock per 100 000 of population	Electrical consumption per head per annum
		kWh
U.S.A.	1	1 100
Canada	0·4	1 500
Great Britain ..	0·1	220
Holland	0·2	160

We have now surveyed a limited field, admittedly in a hasty way, but we can, I think, now draw some general conclusions of interest and value. First, there is a very marked difference in the incidence of electrical risks upon different peoples, and, secondly, the risk does not necessarily increase in proportion to the rate of use of electrical energy.

If one had the time and opportunity to collect for each country information as to the proportions of industrial and non-industrial accidents, and to analyse the causes of both types of accident, and if this information were studied in the light of the constructional rules and methods in force in the various countries, it would no doubt be possible to account for the differences in risk rates in different countries in a more or less satisfactory way. Valuable as such a detailed and comprehensive analysis would be, my purpose to-night has been sufficiently served if I have established clearly that the rates of electrical risk differ widely in different countries, and that in none of them is there as yet any sign of general public protest that the risk rate is too high.

I have already pointed out that, up to a point, the people as a whole are satisfied to leave the setting of standards of risk to their expert advisers. Thus we electrical engineers are confronted by the difficult task of trying to strike a true balance between the two elements of cost of electrical applications—cash and hazard.

I would submit, for example, that the electrical accident rates of 1 per 100 000 of the population of the United States, and of 0·1 per 100 000 of Great Britain, are difficult to reconcile; either one is much too high or —and I say this with considerable trepidation—possibly the other could be suffered to increase. Whether we like it or not, it is our duty as the advisers of the general public to form, and to act upon, a definite opinion as to the magnitude of the risk rate that can be regarded as reasonable.

Here I must take great care to prevent any misunderstanding of my arguments. Let me say, then, as clearly and as positively as I can, that I deplore as much as anyone the avoidable loss of a single life. But I am trying to deal with the world we live in, and the fact remains that avoidable loss of life is continually taking place. Mankind in the mass does not hesitate to accept risks to life and limb if there is enough to be gained by the venture. If the cult of "Safety First" is pushed to the limit we may manage to exist a little longer on the average, but we shall certainly lose much that tends to make life worth living.

We often hear the sentiment expressed that human life is of infinite value, above and beyond all monetary price, but though I shall be talking later in terms of money I am not trying to strike a balance with life in one scale pan and gold in the other. Looked at in the proper way, the problem is an effort to balance correctly human life against human life, years of one individual's existence lost, set against a gain in life value for tens of thousands of people, a gain brought about by improved conditions.

I am not advocating that we should incur more risks in electrical applications; I am trying to survey the ground to see what justification, if any, the electrical engineers (who are morally responsible) have for increasing the hazards of the general public, offering, as recompense for the greater risks, improved and cheapened facilities.

This is an issue that we electrical engineers must face. How can we begin? It will readily be agreed that in attempting an investigation such as this we must go on statistical lines. Individual cases, except as grist to the mill that grinds out the average we are seeking, must either be forgotten or met with the reminder that we are looking for the greatest good of the greatest number and are prepared in our search to appear callous if only we can be clear.

In order to be able to put our findings to practical uses, however, we must make a conversion into money, because the hard facts of the case are, that acceptance of increased risks enables us to cheapen construction costs.

The first step in the investigation, then, is to try to express our time losses and gains in terms of money. Let us suppose that we ask an actuary, a member of that profession accustomed to dealing with human probabilities in the mass from a monetary point of view, "What value do you place on human life?" The answer, I imagine, would be something like this: "The estimated value of a particular human being at a given time is the difference between the present value of his probable future earnings and that of the cost of his future personal needs; in a nutshell, the probable surplus available after he keeps himself."

I attempted to collect some information as to the average earnings in Great Britain, but I was not very successful. I found from the Income Tax reports that the average income of those people who make returns in Great Britain was about £500 per annum, but this figure does not include wage-earners whose gross income does not reach the exemption limit. My very rough attempt to include all wage-earners gives a figure of about £250 per annum for all incomes. Later I found a reference to an estimate by distinguished economists that the average income per head in Great Britain for 1924–5 was £84. At any rate these figures give us a clue to the order of the magnitudes concerned.

If, by any means, we can form an idea as to the probable accident rate due to a particular change of conditions, we are in a position to form an estimate of the cash cost of the risk, for we have evidence in Table 2 as to the probable age of the victims, actuarial tables will give to a close degree of accuracy their expectation of life, and we may safely assume that they will probably be men and earners. I do not wish to labour the point, and I have perhaps sufficiently indicated that it is possible to estimate, it may be very roughly, the actuarial cost of electrical accidents.

To crystallize our ideas, let us assume that a fatal accident occurs to a man earning £250 per annum, whose expectation of life is such that his actuarial cash value is £5 000. Now there is a vast difference between the absolute and irrevocable loss of a life, and the gain in the amenities of other lives, and it is necessary to make some provision in our inquiries for this outstandingly important fact. In many engineering calculations we use a factor of safety, a factor that increases as our ignorance of the real values of the quantities involved increases, and that increases also according as risk to human life is involved in the issue. In attempting to balance loss of life against increased amenities we must introduce a factor of recognition of the vast differences between the two things. I have called this factor, tentatively, the "vitality compensation factor."

Much more detailed examination than has been possible to-night would be required before I dare attempt to assess its magnitude—it may be 20 or 50 or 100—but to show how it would operate, suppose it to be 50. Then for constructional estimate purposes the cash value of our man of actuarial cash value £5 000 is 50 × £5 000 = £250 000. I know this sounds very materialistic, but let me remind you that overhead high-tension lines are being erected all over the world to-day because they are cheaper than underground cables, and we all know that with open lines fatalities which are impossible with cables are bound to happen.

I have only one more point to touch upon. The question arises: "Assuming that an increase in electrical risks can be faced, in what way do we propose to relax our precautions?" Well, I imagine that most electrical accidents are due to one or more of the following causes: Bad design of equipment; bad workmanship; ignorance; carelessness; recklessness; forgetfulness.

Real risk to the ordinary user of electrical facilities should be removed as much as possible by attention to design and workmanship, but it is at least debatable whether we are not going further than we should in protecting people against the consequences of their own recklessness or avoidable ignorance.

There is too, perhaps, a tendency to guard against extremely remote contingencies, against risks that arise only with two or more simultaneous failures of plant or personnel, each failure highly improbable in itself. Unfortunately we can only find out whether the seemingly remote contingencies really are remote by accepting, at least for a time, indeterminate risks.

With that I close my plea for a critical examination of electrical risks. I do not pretend to have done more than indicate a line of thought that may be worth following up, but I do feel that it is essential that we electrical engineers should, in this matter of risks, as in other matters, know what road we are on, how fast we are travelling, and why.

NORTH-EASTERN CENTRE: CHAIRMAN'S ADDRESS

By B. A. ROBINSON, Member.

"THE NEED OF MEASUREMENT."

(*Address delivered at* NEWCASTLE, 21*st October*, 1929.)

One important function of this Institution is to afford opportunities for the experience and knowledge of the electrical profession to be gathered together. The results can then be considered from many aspects before being consolidated and made available for posterity. This is especially necessary in any branch of knowledge where the growth is rapid. It follows that the majority of our meetings and discussions are concerned with technical questions whereby attention is concentrated and directed for the time being on to a certain field of view of small limits. It is not undesirable that your Chairman's address each session should tend to be the reverse and that it should deal with a wider survey, although necessarily briefly.

Whatever may be our outlook on the ultimate meaning of life, it will generally be agreed that we find ourselves in what appears to be a boundless treasure house containing a profusion of treasure, romance, riches and surprises in the most wonderful and bewildering array. In this treasure house we appear to be vital, all-important units, although we are only visitors for the time being. At the same time, although we are fully aware of our separate existence as individuals, we know also that we each form only one unit of a vast confluence of ever-moving units which are changing more or less constantly. On reviewing our knowledge of the history of past ages, we are sensible of the development of a faculty for the appreciation of the treasures and wonders around us. The growth of this faculty has not been uniform. At some periods it has been slow, indeed almost stagnant; at others it has been more rapid, and it is so rapid at present that it is difficult to appreciate its full extent, even without considering details. This cognition, not only of vast treasures, but also of minute elements, is what we call the work of science.

It is the function of the engineer to recognize the practical applications of the discoveries made by the workers in pure science and to utilize these to further the well-being of the community. He has to understand and use to the best advantage the materials which Nature has provided, and he has to develop the various forms of energy which are available.

The development of rubber will occur to everyone as an example of the use of material. It is only about 150 years ago that rubber was first obtainable in commerce, and then only in an insignificant quantity. To-day it is adapted to innumerable uses under various forms. On the other hand, we cannot forget Michael Faraday's fascinating experiments in 1831 when he moved magnet to coil, or coil to magnet. In some respects these seem simple to us now, but when we see the outcome in our modern transformers and alternators we find that they are epoch-making. Again, in 1865, exactly 200 years after young Isaac Newton made some of his brilliant mathematical discoveries, we find Clerk Maxwell using the outcome of those same mathematics to make known the original conception of electromagnetic waves. Compare that mental picture with the universal utility of modern radio communication.

The nation which possesses an active, able and far-seeing body of engineers is well equipped for the battle of life. In thus thinking of the universe in relation to ourselves, we must remember that we are a privileged section of the great family of man. It is our function, privilege and duty to develop the capacity of the whole of mankind to appreciate, to use and, we hope, to benefit by, the bountiful gifts of nature discovered around us.

Mention must be made of the indispensable co-operation and concurrent effort of those working in research and those turning the results of research into practice. This team work inevitably results in further problems to be faced. We find ourselves reciprocating, as it were—some frequently, and others at more leisured intervals—between searching into the unknown, and improving and making more valuable that which is known.

Both to the worker in pure science and to the engineer two qualities are essential, firstly, that of adventure, and secondly, that of dogged determination. These must be maintained in order that a consistent, truthful conclusion may be arrived at, in spite of difficulties, conflicting factors and much disappointment.

We, as engineers, do not lay nearly enough emphasis on the necessity for a courageous spirit of adventure in our work in order to develop still greater enthusiasm in the younger men who will carry on the work at which we have so imperfectly laboured. The driving powers of these qualities are very well illustrated in the life of Faraday. His biographers state that "a new fact seemed to charge him with an energy that gleamed from his eyes and quivered through his limbs and, as by induction, charged, for the time being, those in his presence with the same vigour of interest." When first he saw experiments on the action of a magnet on electric discharges in vacuum tubes, Faraday actually danced around and cried "Oh, to live always in it." A friend once met him in the midst of a tremendous storm at Eastbourne, rubbing his hands with delight because he had been so fortunate as to see lightning strike a church tower.

Faraday's spirit of enthusiasm and adventure led him to investigate any phenomena, regardless of his own welfare. It is not generally known that, in spite of his far-reaching and epoch-making researches in physical science, he found time, in 1818, to carry out experiments on himself on the effect of inhaling ether vapours, thus doing early and important work on anæsthetics. His overwhelming energy was not spasmodic. "It was a lifelong strife to seek and say that which he thought was true, and to do that which he thought was kind." We also should be adventurers with imaginative, constructive minds, using unceasing and careful observation. We seek a clear and honest interpretation of the many bewildering manifestations around us in order to make available for others the powers of Nature. We keep our survey before us and, as we carry out our work, we compare notes of that which we call experience. In so doing we find that our individual knowledge has much in common. We are involved in a process, not only of discovery and development but also of comparison. Henry Cavendish in 1773 conceived the idea that various electrical conductors possessed different degrees of conduction—the early conception of electrical resistance. His method of comparison was to pass the discharge of a condenser through such a length of the material as would give a "shock" which felt the same in each case. The "shock absorber" was his devoted and faithful servant Richard.

The fact that there are many degrees of appreciation was apparent to the early workers long before the advent of so-called modern science. The gradual progress of clearly defined knowledge resulted in the birth of a process of comparison with recognized, determinate quantities. The origin of the British standard of length—the imperial yard—was the length of the arm of King Henry I. In those days, actually, not so long ago, there was no need of fiducial points, or of a temperature coefficient.

From crude beginnings the necessity for comparison has resulted in the building up of a technology of universal importance in its applications. Moreover, its evolution has been extremely rapid of late years. This applies, not only with regard to its ramifications, but also in its advancement from simplicity to comparative complexity. Hence it is a department of science which now is left strictly to specialists.

Here it is opportune to note the difference between comparison and measurement. An illustration may make this clear. We can compare a statue of Haig with the treasured memory of a great British soldier and gentleman. The mental picture may even be assisted by highly accurate arts such as photography or speech-recording. Only a comparison can be made, however, and, as recent events have shown, that comparison may be a matter of considerable difference of opinion. There is no possibility of measurement. On the other hand, observers with quite different outlooks as regards beauty would agree to within extremely small limits when the weight of bronze in the statue is compared with an equal weight of discs bearing the King's image and superscription. The latter is true measurement.

Music affords us with another example. There is a precision of a high order of measurement in its fundamentals, exemplified in the frequency ratios of the musical scale or the relation of pitch to a basis of 256 or 261 vibrations per second for "middle C." Even the temperature correction for tuning forks has been determined to many decimal places. As the theory is reviewed there are the accurate time-differences of quavers, crotchets and minims. The science of measurement is then abandoned although, ultimately, we come to a modulated succession of sounds which harmonize and please a trained ear, that is, if it is music. Measurement does not differentiate between concord and discord, nor between some so-called music and that designated "a noise," as evidenced by the new Act of Parliament. We cannot conceive of any attempt to measure the tune of so-called "jazz" or Tschaikovsky's "1812" overture. This fundamental difference between comparison and measurement is often overlooked, even by those with long scientific training, in their desire to obtain further knowledge of the problems with which they are confronted.

True measurement may be defined as comparisons made under strict scientific laws. Thus we claim to measure quantities connected with materials which we cannot see, feel, smell, hear or taste, or the power to do work, with an accuracy fully equal to that with which we compare the length of a table with that of a foot rule.

Hydrogen is a gas used in huge quantities in industrial processes of to-day. The assumption is now made that an immense outer envelope of this gas surrounds our own planet. It is thought that our atmosphere, consisting chiefly of nitrogen and oxygen, merges into one of pure nitrogen and then nitrogen to hydrogen and, finally, pure hydrogen. Anyhow, hydrogen in its normal state possesses no property which affects our senses. In fairly large quantities it can readily be detected by chemical methods, but the chemist has great difficulty in arriving at a fairly accurate estimate of its purity when dealing with small quantities or weak dilutions. On the other hand, an accuracy of 1 part in 1 000 can easily and quickly be measured by the purely electrical method of noting its thermal conductivity.

When we come to the perception of colour, shape, taste or beauty, we cannot measure in terms of C.G.S. units. We can only compare in terms of human experience—the greatest gift we possess, but one which, as far as we know, does not conform to scientific laws.

All measurement is a system of comparison. Some measurements are simple, especially when an approximate comparison only is required. Take, for example, the quantities of milk, coal and general foodstuffs delivered each day to our homes. Others are complicated in nature and difficult to obtain to a high degree of precision. The methods of comparison can be divided into two classes; firstly, those made to determine the ratio as compared with some fundamental principle, or against a recognized unit. These are called standard measurements, and secondly, those made in vast numbers, especially in industrial processes, to give information of certain empirical conditions. Examples are the grading of cast iron by the appearance of fracture, and the hardness of steel. The first are usually known as absolute measurements, and the second as empirical measurements. From certain points of view, especially that of accuracy, these terms are misleading; empirical measurements are often more accurate than some standard or absolute ones.

The measurement of temperature is one of the most common standard measurements. It is difficult to think of any industrial process in which the measurement of temperature is not involved at some period. It is, however, a peculiar measurement as it is one which conveys no idea of magnitude from a material point of view. It corresponds to the attempt to form a mental picture of electrical energy when one knows only a figure called voltage. Most people, however, unconsciously connect other totally different factors when speaking of temperatures.

The standard of measurement is the difference of temperature of any quantity of pure water when under a pressure of exactly 1 atmosphere between the points of conversion into a solid and into a gas respectively. This interval of temperature between the conversions into ice and steam is called the fundamental interval. Measurements to this fundamental can be made with considerable accuracy over only a small range of temperature. Up to about 500° C. the uncertainty is about 0·1 deg. C.; at 1 000° C. it is 2 deg. C. The melting point of platinum at about 1 750° C. can only be given to within 10–15 deg. C. Coming to temperatures of the melting point of tungsten and that of the electric arc, which represent the highest terrestrial temperatures, we cannot justify our measurements of 3 300° C. and 3 500° C. to nearer than at least 50–60 deg. C. It must be remembered that these figures are obtained with the best precision instruments used under laboratory conditions.

When we are concerned with measurements of temperature outside our own planet, the accuracy of measurement can be compared with the firing of a rocket to the moon. The rocket, with its trail of light, will probably go in the right direction if properly aimed, but how far it goes we cannot say with any precision.

The last 50 years have witnessed a great advance in the science of measurement, due to three outstanding factors:—

(1) The application of genius and of scientific principles to the design of measuring apparatus.

(2) The increase in the number and variety of materials, possessing widely different physical properties, available to the designer.

(3) Precision methods of manufacture, allowing reproduction of a desired shape to within small limits of tolerance, comparatively quickly and at fairly low cost.

The modern development of instruments has allowed knowledge to be consolidated on a much higher level, far beyond the wildest hopes of anticipation of the workers up to the middle of the nineteenth century.

Precision instruments have been the means of opening up immense stores of new information, some of which has been seized upon quickly by the engineers and passed on for the general use of humanity. New instruments can be compared with expeditions of exploration—they give not only greater outlook of vision but also, what is equally important, new combinations of facts.

It does not always follow that the discovery of a hitherto unknown principle and the application of that principle to everyday use can be embodied in a measuring instrument. In fact, the disappointment is often great.

To state that the thermionic valve has revolutionized radio communication is to express the fact mildly. This valve in its many forms is a highly sensitive device with several different functions of use. As a measuring instrument its application, contrary to the expectations of the general community, is extremely limited. This is due to the fact that, in its present form, the thermionic valve embodies several variables in its operation and at the moment it is difficult to separate these factors with sufficient accuracy to enable the valve to be used as a measuring instrument.

The photo-electric cell is another example. An accurate connecting link between the intensity of light and the conduction of electricity has long been desired. The highly exhausted globe with its metallic conductor in front of, but not shielding, a light, sensitive surface, appeared to fulfil this wish. The cells have many applications, but to the specialist in measurement the problem is still an unfulfilled expectation. At the same time, considerable use is being made of this device in applications where only comparison is possible at the moment. We all know something of the problem of smoke abatement; the photo-electric cell is helping towards its solution. Another application is in densely populated areas like London and New York where the wane of natural illumination, due to various causes, is signalled to those responsible for artificial illumination, who can then take the appropriate steps.

The development of coloured materials has reached such a stage that it is difficult even for well-trained eyes to differentiate between different shades of colour. In these cases the photo-electric cell enables comparisons to be made with a standard tint. Similar uses are found in the grading of photographic plates and the comparison of light intensities, especially in meteorological and astronomical work. Conversely, an instrument designed for a limited purpose may with little modification be adapted to give accurate information of far-reaching consequence. A seismograph is an instrument especially designed to record minute impulses imparted to the earth's surface by various terrestrial changes and upheavals. At first sight it would appear that such an instrument would be of little use in the development of oil ultimately to be used to drive our aircraft and motor-cars, or even to set electricity in motion through the agency of oil-fired boilers. Crude oil often is found under a well-defined physical structure of the earth known as a "salt dome." The seismetric method of surveying is based on the fact that sound travels through air at an approximate speed of 1 100 ft. per sec.; through ordinary surface formations at about 6 000 ft. per sec.; and through the highly elastic salt domes at about 16 000 ft. per sec. Hence if a small charge of a few ounces of an explosive buried, say, 7 to 10 ft. deep, is exploded, a compressive wave will travel outwards in all directions. A simple seismograph will record the movement due to the wave. The instrument is fitted with an oscillograph so that, by means of a wireless wave, the actual time of the explosion also is recorded. The time of arrival of the seismic wave is recorded on the seismograph later. If from the record it is deduced that the velocity of the wave is of the order of 6 000 ft. per sec., then it may be inferred that no salt dome exists between the points of measurement. If the velocity measured is greater than 6 000 ft. per sec. there is reason to suppose that a dome may be present or that there is some fundamental difference in the structure of the lower rocks. By employing several seismographs placed in different directions, and also at different distances in the same direction, it is possible to deduce the presence and, roughly, the shape and location of the edge of a salt dome. This illustration of geophysical surveying also draws attention to two important factors of the need of measurement. One has already been mentioned, namely that of exploration and the finding of new combinations of facts. The second now claims our attention.

In dealing with measurements of electrical phenomena it is especially necessary to revise our outlook continuously, particularly as regards our fundamental assumptions, in order that the knowledge deduced from such measurements may be comparable with the general trend of perception in the science.

We cannot, as far as we know at present, actually measure electricity in any shape or form. At the best we can only obtain information of a relationship of the phenomena it produces under certain conditions. These phenomena always include energy in extremely rapid motion. Electricity at rest is not measurable—it is zero with us. At the same time our own faculty of perception—our mind—is only of use when it is in a state of activity, apparently an activity of great rapidity of change. A mind at rest is a blank to us; that is, it is meaningless. Hence, in dealing with electrical manifestations it appears essential that both that which is to be measured, and the perceiver, should be in a rapid state of change. Imagine a number of cameras all focused in the same direction but freely and rapidly moving at random to each other. If they are pointed at a fixed or slowly moving object, and if the shutters are simultaneously released, it is not a difficult matter to assemble the resultant photographs to give a more or less true perspective picture of the single object. If the same collection of moving cameras is now sighted on to a large number of rapidly moving objects—for simplicity a number of balls—it is extremely difficult, if not impossible, to piece the resultant photographs together to give an even approximately true picture at the instant of exposure.

This point of view may appear to be converging too much towards pure science as distinct from practical engineering, but it is necessary for us to realize these limitations if we are to form correct mental pictures of the relationships we wish to establish, especially in connection with space, time and motion. It also helps us to understand the outlook of the modern development of electrical measurement. We are not satisfied with the simple stationary lantern-slides of our boyhood; the demand is for a wide outlook—the moving, "living" pictures Let me give two examples. One of the problems of the extended development and distribution of large quantities of electrical energy at high potential is that of rapid control and interruption. To test the breaking capacity of a switch it is not in any way sufficient to put an ammeter or wattmeter in series with it. It is necessary to measure, at the same instant of time, the changes in a considerable number of phenomena in order to form even an approximately correct mental picture of what actually takes place at the period of operation. One practical result of such knowledge obviously is that still more reliable and efficient switchgear can be built—what might be termed "pedigree switchgear." Similarly with modern alternator testing. In the early days in a test house it was considered to be good practice to use an ammeter, voltmeter and tachometer at the same time, and many anxious moments were spent in trying to get the three elusive pointers consistently steady at the same time in order to log three pointer readings. Pointer readings they were and, as a result, we thought we knew something of the idiosyncrasies of alternator design. To-day a short-circuit test demands all the skill of the instrument maker, combined with the mature experience of the engineer. In spite of the large number of measurements now made, the demand is for more records, with less delay in obtaining such records, and the more accurate synchronism of the measurements.

It is the perception of these necessities which has been largely instrumental in the establishment of national, co-operative, and individual research departments, which already have done, and are doing, work of great importance. Unfortunately this fact is not appreciated by a large number of manufacturers or by the "man in the street" who ultimately obtains the benefits of their labours.

The application of the above-mentioned principles to instrument construction has enabled precision methods to be adopted in increasing numbers in our workshops. The instrument of the laboratory rapidly becomes the workshop tool. The difficult physical conditions under which the measurements are required to be made often necessitate substantial modifications in design. It is necessary to convert the high-precision laboratory instrument, having adaptability for many uses and entailing skilled manipulation, to an instrument in which the accuracy is of a less high standard of precision but which will withstand the difficult conditions of the workshop, requires the minimum of attention and gives readings which can be readily interpreted by the workman. The same argument holds good when we apply laboratory methods to the necessities of everyday life. An example of this is the measurement of electrical energy, with its different components of current, voltage and phase, by means of the reliable, compact and cheap supply meter now fitted in consumers' houses. Two large industries are growing with tremendous rapidity, both of which are of immense importance to the community, inasmuch as one affects the production of food and the other provides essential clothing. These industries, namely the fixation of nitrogen from the atmosphere and the production of artificial silk from vegetable fibre, would be impossible from a commercial point of view were it not for the immense knowledge and control given by the use of instruments. In the synthetic ammonia industry the first essential is to have pure hydrogen and nitrogen. After this it is necessary to control the gas reactions, which vary considerably from one process to another. Not only are there the complicated questions of purity, high pressures and temperatures, but accurate mixtures of gases have to be maintained to produce the requisite reactions and to guard against explosion. In the manufacture of artificial silk, various solvents are essential, such as acetone and carbon bisulphide, the use of which would be highly dangerous, rendering the process impossible if the information which only instruments can give were not available.

The commercial importance of measurement is apparent in another form. The fashion and the passion of the present age is the demand for what, from the purely physical measurement point of view, is designated efficiency—the demi-god at whose throne many engineers appear to worship. It is measured by the ratio of useful work attained to the energy expended, the latter, however, from the purely materialistic point of view. It is admitted that efficiency is essential to enable most processes to be carried out for a purely financial end. There is a danger, however, that no allowance is made for the physical and mental energy expended by the personnel. In the past, human life was reckoned cheaply in terms of ignoble toil, then called slavery. The tendency to day is to sacrifice human life to speed and noise; that is, unedifying mental slavery which is hardly conducive to increased happiness.

Within recent years there has been an increasing demand for the use of instruments to effect automatic, or at least semi-automatic, control. Important strides have already been made and consistently reliable results obtained. The engineering problems involved are of a distinctive character. The laws of economics demand units of large size, transforming large quantities of energy, in order to obtain so-called efficiency. The alterations necessary to control appreciable amounts of energy likewise necessitate the expenditure of moderately large amounts of power. Conversely, the control instrument has available only a very small amount of power to operate any other device, with the result that generally several relay stages, each possessing necessary characteristics, have to be interposed between the point of measurement and the actual control gear.

Our ideal of being able to provide electrical energy, with all the advantages which this entails, at a moderate cost to the major portion of this nation is being realized to some extent by the installation of the grid system or systems. An essential factor in the scheme is the provision of automatic control of distribution. The solution of this problem not only entails accurate measurements but is dependent on operations being carried out in a correct sequence and with certain prescribed time-intervals. The fact that instruments can be utilized to control consistently such complicated operations reflects considerable credit both on the physicist and the engineer. In some respects a more advanced stage in the development of control has been reached by the growth of automatic telephone systems whereby the transmission of information, and therefore the general mental intercourse of mankind, has been accelerated. It was brought to my notice recently that, in an hotel in Barcelona, a telephone is provided in each bedroom, with an accompanying notice in several languages stating that, by its use, communication could be established with any telephone user in Great Britain, France, Germany, Italy and Spain.

In connection with a number of industrial processes, there is a necessity to effect automatic control of only one physical condition at a time. The first essential is to effect uniform local conditions rather than to attempt to obtain accuracy to the fundamental standards. It is agreed that in most cases there will be a constant relationship between these empirical conditions and an absolute measurement, but it is rarely necessary to deduce this factor. In order to secure a uniform product one must have uniform conditions of treatment. Thus the heat treatment of materials to within the close limits obtained to-day would be impossible were it not for the skilled application of temperature-measuring equipment coupled with automatic control gear. In industrial furnaces heated by gas, oil or electricity, there is no difficulty in controlling the temperature to within less than 1 per cent up to temperatures of 1 400° C. In special applications appreciably better control can be effected; for example, it is possible to maintain astronomical instruments under practically constant temperature conditions all the year round.

It may not be generally known that fruit from abroad can only reach us in the perfection to which we are accustomed, by the automatic control of the carbon dioxide content of the atmosphere in which it is stored. In the case of tobacco it is a question of the control of humidity. In a similar way other physical conditions can be controlled. An important but indirect outcome of these methods is the large saving in energy effected, and this helps to reduce the cost of production.

Although the widespread use of instruments as workshop tools, and the ideals of automatic control have produced, and are increasingly producing, enormous material and economic advantages to mankind, there is a distinct loss from another point of view. It is a loss which is difficult to estimate or, at present, to realize fully. The mechanical control of production has a tendency to cause the human beings employed to become simply parts of the machine. Workmen are thought of as mere units to be drawn from the pool of so-called "labour." It is the knell of passing craftsmanship. The loss of craftsmanship means the loss of the beauty of human experience expressed in material form.

We must keep ever before us the broad visions of our relationship with our fellow men, what we owe to them and what they expect from us. We must take care that we do not so closely concentrate our vision that in reality we become only a part of the machines for which we are responsible. We must not be parts of the instruments we use nor must our minds be the real charts. Some words written by Sir Isaac Newton shortly before his death are still true. He wrote " I seem to have been only a boy playing on the sea-shore, and diverting myself in now and then finding a smoother pebble or a prettier shell than ordinary, whilst the great ocean of truth lay all undiscovered before me."

We find the good in life because we search, and because we train ourselves to overcome difficulties. We gain experience, ungrudgingly pass it on and render it available for others. Each one possesses a measure of craftsmanship to some extent different in outlook, in power of execution and in application. Collectively, however, we do our best and offer it for the benefit of mankind.

If the spirit of Faraday with all his kindness and sincerity and, above all, his enthusiasm and wide vision, is in each member of this Institution then we may take courage, we shall not lose our vision and we shall go on in the adventure and the conquest of the secrets of Nature.

NORTH-WESTERN CENTRE: CHAIRMAN'S ADDRESS

By T. E. HERBERT, Member.

"INLAND TELEGRAPHS."

(*Address delivered at* MANCHESTER, *22nd October*, 1929.)

When the Society of Telegraph Engineers was founded in 1871, the telegraph was the only practical application of electricity. In course of time, however, interest turned towards electric lighting and power and the present more general and all-embracing title of the Institution was adopted. To-day, the advances in telegraphy and telephony have rendered these subjects particularly interesting and it is, I think, correct to say that recent developments have been of a radical nature unparalleled in any other branch of electrical engineering.

The telegraph and telephone systems of any country should be regarded as a whole rather than as separate services working in "watertight compartments." In Germany the whole of the telegraph line-plant had disappeared by the end of the War and the system had perforce to be re-established by utilizing circuits in telephone cables. I have chosen the subject of inland telegraphs for my address and have deliberately excluded from my review the Continental telegraph circuits because these services are self-supporting and show a definite profit. It will, however, be useful first to give a very brief outline of the development in telephone engineering so far as line plant is concerned.

The advent of the paper-core cable made it possible economically to provide large numbers of wires, to say nothing of the better transmission secured. For telephone subscribers' circuits the largest cable which has been made for drawing into a 3¼-in. duct contains 3 636 wires. The work of Heaviside and Pupin gave us the loaded cable. This advance brought with it new problems and it became necessary, after the cable was laid, to measure the capacity unbalances of the circuits, length by length of cable. The technique of these operations was devised and developed by the Post Office Engineering Department.

Quite recently a definite advance has been made in telephone cable design. In the star quad cable the 4 wires of each core are twisted together in one operation and so occupy the 4 corners of a square. This formation was adopted in the first London–Birmingham cable laid in 1899 but, owing to the instability of the make-up due to the loosely-wrapped pairs, there was very considerable inductive interference between the circuits. In the new cable practically the whole of the insulation consists of paper, and no attempt has been made to provide large air-spaces. Stiffening of the paper tubes has resulted in accurate and permanent centralization therein of the conductors, whilst a central string upon which the covered conductors are bedded ensures symmetry of the cores. This extremely important feature of centralization of the conductors within the paper tubes may be secured either by the use of specially creased or corrugated surfaced-paper wrappings, or by a spiral whipping of string directly adjacent to the conductor, over which the insulating paper is tightly wrapped. The cable is, therefore, extremely compact and uniform in its behaviour. For example, a 254-pair (127 quads) cable can now be drawn into a 3¼-in. conduit, as compared with the former standard 160-pair multiple twin cable.

Until the advent of the thermionic valve the telephone repeater was not a practical possibility, and consequently the distance over which speech could take place was very definitely limited. With its aid we can now speak all over the continent of Europe and, by the use of wireless, across the Atlantic.

A telephone cable bridging the Atlantic, with a repeater station at the Azores, is projected. Another suggested cable is from Cadiz to Pernambuco with repeater stations at Teneriffe, Cape Verde, and Fernando Noronha. One of these cables will have paper-insulated conductors with a double lead sheath. The main trunk telephone system of this country is now of a most extensive character and is almost wholly underground.

Whilst these developments have been taking place in telephony, corresponding advances have taken place in telegraphy. The first submarine cable was laid between Dover and Calais in 1850, and in general it may be said that a stranded copper conductor insulated with gutta-percha and mechanically protected by iron-wire armouring was the standard form of cable until the application of loading. The discovery of the remarkable magnetic properties of the nickel-iron alloys —permalloy, and its British equivalent mumetal— revolutionized the submarine cable. The stranded copper conductor is lapped with this alloy and its inductance is thereby increased to such a value that the speed of working is multiplied by 6 to 8 as compared with the unloaded cable. The effect of this was to render all previous long submarine telegraph cables obsolete.

The inland telegraphs were bought from the private companies concerned in 1870, and it is now recognized that the purchase price, £11 000 000, was too high, being only 12 per cent less than the amount paid to the National Telephone Co. in 1912 for the vastly larger plant of their telephone system. This purchase price does not, however, explain the loss on our inland telegraphs to-day. At the time of transfer, special rates were inaugurated by which additional copies of Press messages were transmitted at 2d. per copy. This rate applied to copies of messages sent to different towns and was not confined to additional copies in the same place, where the extra copies could be manifolded. Hence a night Press message of 100 words could be sent to 20 different towns at a cost of 4s. 2d. (1s. + 19 copies at 2d. per copy).

On the other hand the improved facilities for news distribution were definitely in the interests of the general public. Indeed, no modern newspaper could exist without the aid of present-day methods of electrical communication, and newspaper development was in no small measure rendered possible by the cheap Press message. This advantage was shared by the community at large, and it would therefore be arguable that the special concession has been justified.

There is to-day no justification for any such subsidy of the public Press—in fact, all the great newspapers have private wires of their own in order to avoid the delay inseparable from transmission of messages between the Post Office and newspaper offices. In other words, the greater celerity amply justifies the very heavy charges which this policy entails.

Some economy could, and no doubt will, be effected in the case of newspapers having suitable apparatus by switching the transmitting office through to the newspaper office when there is any considerable volume of traffic to be dealt with. At present many long Press messages are transmitted from the main office to the local papers by passing the received perforated tape through the transmitter on a circuit connecting the main office and the newspaper.

Let us now take a glance at the position in 1870, when the Post Office telegraphs were established. At that time no other means of electrical communication existed, and methods of transit were very slow compared with present-day facilities. Telephones have now passed from the state of an aid to business to that of a social and commercial necessity. Railway services are frequent and more or less rapid, and with the electrification of the railways still further acceleration will result. Motor vehicles of all kinds serve to make communication between distant places more and more rapid. Thus it will be appreciated that if a telegram is to take less time between its initiation and its receipt than any method of mechanical transport, such as train or motor car, the telegraph service of to-day must be vastly quicker than was necessary in 1870. It should not be overlooked that the inland telegraph system is the medium by which foreign messages are distributed to the recipients throughout the country, and thus it performs a most valuable function for the community.

Referring once again to the position in 1870, for a message of 20 words the companies charged 1s. for distances up to 100 miles, 1s. 6d. up to 200 miles, 2s. over 200 miles in Great Britain, and from 3s. to 6s. for transmission to Ireland. In addition there were charges for delivery beyond a limited radius. These charges were, at the time of the transfer, reduced to 1s. per message, and the telegraphs were rapidly extended so that, instead of some 500 railway stations, there were 1 800 stations and about 1 000 post offices from which telegrams could be sent. By 1914 the number of offices had been increased to 14 222.

The telegraphs were not developed on purely commercial lines, but as a national service, the aim being to bring every centre of population within the range of communication, regardless of the question as to whether it would pay. Commercial methods would, of course, have resulted in concentration on profitable business alone, and would have left our villages in a continued state of isolation.

A record of the total traffic in millions of messages year by year is given in Table 1.

TABLE 1.

Year.	Total messages	Inland messages

* Transfer to State control.
† 6d. telegrams introduced in 1885.
‡ 9d. telegrams introduced in November 1915.
§ 1s. telegrams introduced in September 1920.

The revenue from the telegraph service has never been sufficient to pay interest on the capital. Of this loss the Press messages represent £225 000 per annum. By 1881 the balance of receipts over expenditure had nearly reached the interest due on the stock. This position was, however, profoundly modified by the introduction of the 6d. telegram in 1885; this reform was carried out deliberately by Parliament in spite of the losses that it was known would occur. Table 2 gives some particulars of these losses.

In 1913, of the total communications (telegrams plus telephone calls) 64 per cent were sent by telegraph, whereas in 1926 the figure was only 36 per cent of the total. On the other hand, in America 150 million telegraph messages were sent over the Western Union system alone during the year, this being 2½ times the number handled 10 years ago. This shows the vast difference between England and the United States in the use of telegraphic facilities. The explanation is, however, quite obvious—this is a small country and the distances are short. If the telegraph is to be quicker than other means of conveying a message the time available from initiation to receipt is much less here than in America, where the distances are vastly greater. The greater time available for telegraphs brings with it differential charges based on distances and also on celerity. The advantage of levelling up the load curve needs no explanation.

The day when every house has its telephone and its motor-car has not yet dawned, even in America, much less in England, and therefore it cannot be assumed that every message can be sent direct by the sender to the recipient, but it is reasonable to suppose that the number which can be sent in this way will tend to increase. A telephone message occupies an individual pair of wires for the whole time that the conversation takes place, whereas several messages can be sent simultaneously on a single telegraph wire by the Baudot multiplex or on a loop by voice-frequency telegraphs. The present tendency is, however, towards the use of sub-audio telegraphs worked on telephone trunk-circuits, or alternatively superposed on such circuits with thermionic-valve reception of the signals. For example, a 4-wire core gives 3 telephone circuits (2 physical and 1 phantom), and over the centre of the phantom a telegraph circuit can be worked without affecting the telephones. At the telephone repeater-stations all that is necessary is to connect across the centre points of the phantom superposing transformers; consequently the plant costs are only a fraction of the similar costs for telephone trunk-lines. There is, however, this fundamental difference, that a telegram has to be signalled by hand, whereas the work of a telephone operator is confined to making and severing the required connections. Hence it is only over very long distances that the telegram becomes the cheaper method of conveying messages. In the case of an Atlantic submarine cable the position is reversed, and the operating cost in human labour is small in comparison with the plant costs. More human energy is employed in the transmission of a telegram than in setting up a telephone call, and on receipt the message has generally to be delivered by hand. In the case of country villages the general use of the telephone by the villagers presents some difficulties, since few of them are connected. Possibly some method of making use of garages for telegraph purposes may be evolved, but it is true to say that the telegraphs in villages are to-day still serving the purpose for which they were originally designed. Incidentally it may be explained that many of these telegrams are transmitted over telephone circuits to the nearest large telegraph transmitting centre and vice versa.

TABLE 2.

Year	Loss
1904	£958 000
1910	£853 000
1924	£1 271 000
1925	£1 645 000 *
1926	£1 299 000
1927	£1 349 000
1928	£1 381 000

* This figure includes £300 000 paid for War services.

Let us now take a brief survey of the apparatus developments. At the end of last century, the main-line telegraphs were worked by sounder, and minor circuits by Wheatstone A B C, single-needle, or double-plate sounder. The Press work was all carried on Wheatstone circuits, generally worked at about 300 words per minute. The Wheatstone A B C was used to work to villages where there was little traffic. Its principal advantage lay in the fact that little or no skill was required to operate it. It was, however, very costly to maintain, and with the advent of rural telephone circuits its use became more and more restricted, and to-day it has entirely disappeared. The needle instrument persisted somewhat longer, since it was capable of dealing with a fair amount of traffic and did not necessitate the highly skilled training demanded by the Morse sounder. It, too, has almost disappeared and is now probably used only by some of the railway companies on their private-wire systems.

The Wheatstone automatic system originally consisted of 3-key perforators, a transmitter and a receiver. The message to be sent is recorded in the form of perforations on a tape; the speed at which this record can be made is about 20 to 25 words per minute. The tape is then passed through the transmitter, which automatically sends out morse signals in accordance with the perforations, at a speed of from 150 to 400 words per minute. At the far end of the line the signals are recorded in morse on a tape by a Wheatstone receiver. If 10 men each perforate at the rate of 25 words per minute and these slips are periodically collected and successively passed through a transmitter running at, say, 300 words per minute, then we have the equivalent of 10 men at each end working direct to each other, but on 1 wire instead of on 10. On the other hand, a man is required to collect the slips and to feed the transmitter, while at the receiving end another man is occupied in distributing the slips for writing up by hand. Hence it will be evident that Wheatstone automatic working is costly in labour but saves line plant. On the other hand, where the same message has to be sent to several towns—and this is characteristic of much Press work—one perforated slip may be passed through several transmitters, and thus several separate manual signalling operations are avoided.

The Wheatstone system was given a fresh lease of life by the design of new machines. Keyboard perforators raised the speed at which the tape could be perforated. Then the Creed receiving perforator replaced the Wheatstone receiver. Instead of dots and dashes inked on a tape, the message was received in the form of a perforated tape identical with the transmitting tape. This received tape can be used to send the message to other stations, or, by passing it through a Creed printer, the message may be typed in roman characters either on a tape or in column form.

While these developments have been taking place, all the great newspapers have arranged to rent lines to

London from the Post Office and to provide their own staff and apparatus. In this way some saving of time is effected, but it has, of course, reduced very greatly the amount of Press work dealt with by the Post Office.

Lieut.-Colonel A. C. Booth, of the Post Office Engineering Department, duplexed the Baudot. This system gives from 2 to 6 channels in each direction over a single wire. In its original form, messages were transmitted by depressing 5 keys in various combinations for each letter. This gives 31 working combinations, and by a device resembling the figure shift on an ordinary typewriter the number of characters is doubled. At the receiving end the message is printed on a tape in roman characters. Here, again, the system becomes expensive on account of the amount of highly skilled attention required. The latest development of this plan consists in providing a typewriter-keyboard perforator for sending the signals from the perforated tape. The advantage gained lies in the higher speed of operation and the absence of the necessity to send out the signals letter by letter in accordance with a time-beat. Moreover, modern receivers enable a speed of 60 words per minute to be attained, as compared with about 30 to 35 with the original Baudot.

We now come to the position to-day. It is quite clear that the Wheatstone automatic system must disappear altogether and it seems equally probable that multiplex systems will also have a very restricted field of utility in this country. In fact morse, whether manual or automatic, is doomed, chiefly on account of its inefficiency in the use of human effort. Here it may be well to remark that the losses on telegraphs would not disappear even if all the plant costs were entirely eliminated, and so the future line of development in so small a country as this will not consist in plant-saving devices such as multiplex, voice-frequency or automatic systems, but in the adoption of methods which obtain equal results with the minimum expenditure of human effort. The deduction from this would appear to be that heavy expenditure on plant is amply justified wherever labour savings can be effected.

At the moment the replacement of all forms of apparatus by start-stop telegraphs is beginning. These instruments derive their name from the fact that a starting impulse precedes the 5 currents composing the code, and the machine is stopped by a current at the end. The machine has a typewriter keyboard and prints the message on a tape in roman characters. The teleprinter 3A, adopted by the Post Office Engineering Department, is the invention and design of Mr. F. G. Creed, of Croydon. It is driven by a small electric motor and depends for its action principally on a battery of cams, the electrical portion consisting only of contact springs for sending and a single electromagnet for reception. It is interesting to notice that telegraphy is very largely mechanical in character, whereas in telephony the mechanisms used are of the simplest nature.

The teleprinter works at about 60 words per minute as compared with 20 to 25 for a Morse sounder, but even this is inadequate to wipe out the loss on telegraphs. The manual re-transmission of messages is necessarily a costly process and it is evident that this must be avoided to the utmost extent. In the early days of telegraphs experiments were made in telegraph switching, but these were abandoned. A comparatively elaborate system existed in Belgium some 30 years ago, and the metropolitan intercommunication system devised by Col. Sir T. F. Purves in 1900, by which sub-offices in London were interconnected at a switchboard to send their messages direct to each other, has only recently been taken out.

In this case the Morse sounder was used, but owing to the decline in messages across London, due probably to the more intensive development of telephones, the system ultimately failed to justify its continuance. It is interesting to note that the first exchange was not a telephone exchange, but a telegraph exchange at Newcastle, working prior to 1870 with Wheatstone A B C apparatus. In 1884 it was converted to telephones.

This brings us to the final stage, in which it is pertinent to consider what is likely to be the line of future development. I suppose it is generally unsafe to attempt prophecy: nevertheless I will venture to describe what I imagine will be the function of telegraphs some 20 or 30 years hence.

In the first place, the business community will have discovered that speeding up their methods will enable more business to be done with much less effort. There will, moreover, be such legislation in vogue as will prevent the recurrence of frequent financial upheavals, and people will thus be enabled to concentrate on useful work. Much more attention will then be available for concentration on doing the job in the simplest, quickest and most direct way.

Every business office will be equipped with a teleprinter and, by means of a dial form of automatic switching, communications will be sent direct to the recipient. All businesses where the office staff possesses even one typist will have the machine installed. In the case of very small firms, possibly, the telephone connection may be used for the dual purpose, or perhaps several small firms may share a single telegraph wire. The messages will be received on a form of receiving perforator in the main telegraph office of the town to which the recipient is connected, and in this way the message will be stored and automatically sent to the recipient as soon as his circuit is free. Several machines may be "lined up" on a rotary line-switch with messages for a single subscriber and will discharge their messages in sequence. This plan will enable the messages to be dealt with in a strictly routine manner. The telephone will, on the other hand, be used where discussion is essential, and all trivial inquiries addressed to important executives personally will be eliminated. Much time is wasted by inquiries addressed to particular people known personally to the caller for detail information which the executive has to obtain in a hurry while the telephone call is proceeding.

A service of the type I have sketched will need a large number of circuits, but these are already available, since it has been demonstrated that telegraphs can be worked at sub-audio frequency on telephone trunks without appreciable deterioration of the latter. When this source fails, voice-frequency systems, or even multiplex systems, controlled by precision vibrators as regards the division of line time, will certainly meet requirements.

There remains the problem of the delivery of messages. For the purely private message where the recipient is not on the telephone—and the percentage of such messages to the total messages would tend to decrease—there seems no alternative to delivery by messenger. If, however, the system as a whole can be made remunerative this does not seem a very serious matter.

The advantages of the plan I have outlined consist in transferring the human labour to the subscriber, but this does not represent any serious addition to his necessities, since the message can be telegraphed with no more labour than that involved in typing the corresponding letter.

That the development I have postulated is by no means improbable or visionary is exemplified by the following extract from the *Wall Street Journal*, 27th July, 1929:—

"*Bell System's New Invention.*

" Typewriter-Telephone Service eventually may compete
" with Telegraph. Device seen in Demand.

> " The Bell System has developed a telephone typewriter which provides equipment and circuits, and gives a service which permits subscribers to handle their own messages, telephone or telegraph, in their own way. Telephone typewriter instruments have to a large degree the flexibility of telephone instruments, and can be interconnected through suitable switchboards in the same manner. It is, therefore, quite feasible to provide a large number of subscribers in their business offices with these instruments, and to furnish wire interconnections between these subscribers as they may indicate their desires. The service need not be confined to a single city, but any subscriber in New York may be connected to any subscriber similarly equipped in some other city, the time required to complete this connection being of the same order as that required to complete a telephone connection between the same two points.
>
> " A service of this character is analogous to present telephone service in that the subscriber would, in general, provide his own telephone typewriter operator and on the completion of the desired connection to the called subscriber would handle his messages in any way that he saw fit.
>
> " An experimental service of this character has been established between switchboards and stations installed in telephone company offices in New York, Boston and Chicago and some adjacent cities. When placing a call, the subscriber merely switches on the power at his station, which is analogous to lifting the receiver from the hook. This operation lights the line lamp at the telephone switchboard and the operator responds by connecting his telephone typewriting instrument to the calling subscriber's line and writing the letters, for example 'NY OPR.' The calling subscriber types the station connection desired and awaits response from the called subscriber or from the operator if the connection cannot be completed.
>
> " It is obvious that the American Telephone and Telegraph Co. could become a competitor of the telegraph companies at will, but so far the company has concentrated its efforts entirely on the telephone and has contented itself with leasing its facilities for telegraph purposes. A new phase now enters the situation in the shape of the new telephone typewriter exchange service which is being developed by the American Telephone and Telegraph Co. which may become a factor in the telegraph field.
>
> " The Bell System engineers are perfecting the switchboard device and there is some experimentation yet to be completed, but it would appear that this form of typewriter telephone development is going to become a potent factor in the communications field in the not far distant future."

It only remains to add that salesmanship and adequate publicity are clearly essential to the early realization of such a scheme. The engineering details would present no insuperable difficulties, but it may be interesting to point out a few other possibilities. Firstly any telegraph message sent by telephone, either from a telephone subscriber, a telephone kiosk or from a village post office or railway station, would be typed as it was received at the main telegraph office and would thus be transmitted to its destination; or the typewriter might have a perforating attachment to enable the message to be stored in the form of a perforated tape and so transmitted automatically when a circuit became available.

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE: CHAIRMAN'S ADDRESS

By Professor E. W. Marchant, D.Sc., Member.

"SCIENCE AND ELECTRICAL ENGINEERING."

(*Address delivered at* Liverpool, 21*st October*, 1929.)

In a year which is so near to the centenary of the discovery by Faraday of the way in which an electric current can be generated by the movement of a magnet near to a coil of wire, it may not be inappropriate to survey the progress of electrical engineering which has resulted from scientific discoveries. In this address it is impossible to deal with more than a fraction of the important experiments that have been made in electrical engineering, and the degree of importance of those mentioned below is varied.[*] The last century divides itself into a number of periods, each of diminishing length, in which some great discovery has led to further progress and the development of new industries.

Electromagnetism.

The earliest experiment of importance in electromagnetism is that of Oersted, who was the first to discover the effect of an electric current on a magnet. A very interesting account of his work[†] has recently been published. The currents available at that time were very small, and the deflection that Oersted produced on a compass needle placed near to a conductor carrying current was almost imperceptible.

It is interesting to record that Oersted's first experiment, in Copenhagen, which was announced in July 1820, was made in what is now Telephone House, the headquarters of the Copenhagen Telephone Co.; and the exact point at which the observation was made has now been located. The house itself was partly residence and partly the scene of his lectures. On the day of his discovery, at the close of his lecture, he asked his class whether they would like to observe what might happen when an electric current flowed through a wire placed near to a compass needle. The class remained and witnessed the result, i.e. a deflection of the compass needle when an electric current flowed in a neighbouring wire placed in proper relation to the needle. The movement was so small that Oersted at first attributed it to capricious disturbances. He was perplexed by the movement of the pole in a direction at right angles to the direction of flow of the current in the wire. Why was not the line of movement the same as that of the originating current? Later he returned to the investigation and obtained definite results. Who can estimate the importance of this observation? It opened the way at once to a method of signalling different from that which had previously been possible, and gave to research an impulse as far-reaching as it was momentous. Sir John Herschel, at the meeting of the British Association in 1846, speaking of Oersted's discoveries, said: "The electric telegraph and other wonders of modern science were but natural effervescences from the surface of this second discovery which Oersted liberated, but which was yet to burst with all its mighty force upon the world."

Oersted and Faraday met for the first time in 1823. Each of the two philosophers followed closely the account of the other's researches. The first man in America to emphasize the importance of Oersted's discovery was Joseph Henry, and by 1841 Oersted's name was as well known in America as in Europe. Oersted had a considerable regard for Charles Wheatstone, the professor of physics at King's College, though it took 17 years for Wheatstone to apply Oersted's "beautiful discovery" to the practical electrical telegraph. By 1837 the telegraph was installed on one part of the line between London and Bristol over a length of 14 miles. Wheatstone, writing to Oersted from King's College, London, speaks of "the way in which I have applied your beautiful discovery for the purpose of transmitting instantaneously both visibly and audibly to great distances."

The next epoch in the history of electrical development began when Faraday discovered how to produce an electric current by means of a magnet. So many descriptions of this experiment have been made that it seemed worth while to construct some coils which exactly complied with Faraday's specification.

Faraday first tried experiments on mutual induction; that is, he wound two sets of coils on a paper tube, connected one to a battery and the other to a galvanometer, and noticed that when the current through one was switched on or off an induced current passed through the galvanometer. The next step was to place an iron core inside the coil, and he noticed that the effect was greatly increased thereby. The great discovery was made when he connected all these coils in series and, using two magnets each 24 inches long, placed the north pole of one in contact with the south pole of the other, and the other north and south poles in contact with the ends of the iron bar passing through his coils; and he found that if one magnet was brought into contact with the iron bar a current was induced in the coils and passed through the galvanometer. It was then a simple step to the discovery that a current was induced when a magnet was thrust into the coil. Such was the series of experiments, as described in the *Proceedings of the Royal Society*, which Faraday performed in 1831, and which have meant so much to the progress of the material side of human civilization. Nowadays the experiments seem so simple that every schoolboy knows about them, and it is difficult to realize their tremendous importance when they were made. It is worth while to try to do so, however, because it enables one to visualize the possibility of developments of almost equal magnitude arising from apparently insignificant discoveries.

---

[*] In 1927 Sir Ambrose Fleming gave a course of lectures before the University of London which have been published in book form, under the title "The Interaction of Pure Scientific Research and Electrical Engineering Practice," and contains a description of a large number of researches having bearing on electrical engineering practice.

[†] *Electrical Communication*, 1928, vol. 6, p. 181.

There is, of course, a very big step between Faraday's experiment and the 160 000-kW alternators that are being built to-day. There are many men, such as Gramme, Pacinotti, Siemens, Wilde, John Hopkinson and Parsons, whose work as engineers has brought the generator of electrical energy to its present efficiency and size. Although I do not wish to minimize the services of these and many other eminent engineers, it is well to remember that the whole technique of the production of electrical energy could be altered if some means other than the steam boiler, turbine and alternator were discovered which would enable a larger fraction of the energy stored in coal to be transformed directly and economically into electrical energy. All scientific work of a fundamental nature should be encouraged for it is possible that entirely new methods of controlling the electrons, which we now know constitute an electric current, may be discovered. Our knowledge of the fundamental nature of matter has undergone a profound change since Faraday made his great experiment, and it does not seem beyond the realm of scientific possibility that there may be devised some methods of setting electrons in motion other than those with which we are familiar. Already physicists have accomplished things which we should have regarded as incredible 30 years ago, and astronomers have told us that in the interior of the stars matter must be completely broken up into a mass of atomic nuclei and free electrons. Whether engineers will ever be able to reduce matter to such a condition it is not for me to say, but no avenue by which more effective use may be made of our sources of energy should be left unexplored.

Although electrical engineers are concerned primarily with the practical application of physical science, it is well to remember that most of the fundamental physical discoveries were the result of purely scientific investigation directed towards no practical end. A member of the audience at one of Faraday's lectures on electromagnetic induction once asked, " Yes, but what is the use of it?" Faraday replied, as many another wise man has replied, by asking another question: " What is the use of a new-born baby?" As a matter of experience nearly all discoveries in pure science, however useless they may appear to be, find their practical application sooner or later.

CABLE TELEGRAPHY.

Another branch of electrical engineering which had its beginning in a more or less academic scientific discussion is cable telegraphy. The idea of telegraphic communication across the Atlantic was one which had appealed to many electrical engineers, and it was in 1856 that the money was raised which enabled the first cable to be laid, but the theory of cable transmission was not at that time clearly understood. In the early experiments a telegraphist named Whitehouse was in charge, and he thought that the proper method of improving the working was to raise the voltage on the cable, and actually used no less than 2 000 volts in the hope that signals might come through quickly to the receiving end. His method, of course, was wrong, and caused breakdown of the cable insulation. Prof. William Thomson, later Lord Kelvin, who held a relatively subordinate position in the undertaking, went out on the cable ship " Agamemnon " as electrician of the company. He had studied the conditions and realized that the problem of the transmission of an electric current through a cable was similar to the problem of the transmission of heat through a conducting rod or plate. The electrical resistance of the cable was analogous to the thermal resistance of the rod, and the capacity of the cable could be compared with its thermal capacity for heat. He and Prof. Gabriel Stokes worked out the complete theory of transmission along a cable by analogy with the problem of transmission of heat through a plate, which had been investigated by Fourier, and showed what were the factors which determined the speed of transmission. After Kelvin's delicate siphon recorder had been constructed cable telegraphy became a practical proposition, and a great step had been made in practical electrical engineering.

While the cable was being made, Kelvin recognized the necessity for obtaining pure copper in order to reduce its resistance as much as possible. He specified, for the first time, copper of " high conductivity." In order to ensure that the material should be of the right quality he set up at the factory an apparatus for testing it, and founded the first works testing laboratory.

TELEPHONY.

We have celebrated recently the work of Alexander Graham Bell. His serious study of electricity was undertaken with a view to understanding and repeating the experiments of Helmholtz in the artificial production of vowel tones. He set out with the idea of making a speaking machine which would reproduce human speech by the vibration of a series of tuning-forks or flat reeds. The sender of his first transmitter was a steel reed which was kept in vibration by a mechanism similar to that of the electric bell. When the currents from this apparatus were transmitted along a line they set in strong vibration a reed placed opposite to a magnet through the coils of which these currents passed, provided the periods of the reeds at the two ends of the line were the same. His original idea of a transmitter was a harp-like machine with a number of reeds that were set in vibration by the voice and produced currents corresponding to their natural frequency, which, being connected electrically to a series of similar reeds on the receiver, would set them in vibration and so reproduce the spoken word.

It would take too long to describe the steps by which Bell ultimately succeeded in devising the telephone. The discovery that a reed, when set in vibration opposite a magnet, gave rise to currents sufficiently powerful to cause another reed placed opposite another magnet, and tuned to the same pitch, to be set in vigorous vibration, was accidental; and from that the step to the thin iron diaphragm with which we are now familiar was relatively easy.

The discovery of the telephone, however, is an interesting illustration of research begun for purely scientific purposes, followed by the observation of an unexpected phenomenon, and then the gradual development of the idea to a practical result. Who can say what Bell's discovery has meant to the world? When telephony was attempted over distances of more than a few miles the distortion of the speech became so bad that the telephone was practically useless. Heaviside came to the rescue, and in a series of mathematical papers showed how these difficulties could be overcome by the use of inductance.

The mathematical equations for the transmission of telephone messages along a loaded cable are similar to those for the transmission of sound in the sound-box of a gramophone, and the solution that was given by Heaviside for the electrical problem has been of the utmost value to the designers of gramophone sound-boxes.

Electrical engineers can therefore take to themselves some credit for the progress that has been made in the recording and reproduction of sound.

Nowadays we are so familiar with telephony that we perhaps fail to realize the change it has made in our lives. One man can now do an amount of administrative work which would have been impossible without it, and the saving of time and trouble to the ordinary man is incalculable. Now that transatlantic telephony is an everyday event, one can begin to see what an influence the telephone is likely to have on the language of the future. It may tend, perhaps, to counteract some of the excessive nationalism which has been such a depressing feature of European politics since the War.

HIGH-FREQUENCY CURRENTS AND WIRELESS TELEGRAPHY.

I have referred * quite recently to the developments that arose from Lord Kelvin's paper on "The Production of High-Frequency Currents by the Discharge of a Condenser through an Inductive Coil." That paper was really the starting point of wireless telegraphy. I remember, too, a paper † on the direct-current arc, which was read by the late Mr. Duddell before this Institution, in which he showed how it was possible to produce electrical oscillations in an ordinary carbon arc by shunting it with a condenser and a coil. At that time it seemed a very interesting experiment with very little practical application; but it was found by Poulsen that if the arc burnt in an atmosphere of hydrogen and in a strong magnetic field, the frequency of the oscillations which it produced could be raised to values which might be applied in wireless telegraphy, and its utility became apparent. At the time of the War the Poulsen arc, as it is now generally called, was the best means known of producing continuous high-frequency oscillations. Nowadays it has, of course, been replaced by the valve.

One of the first papers on the valve was read before the Royal Society by a Past President of this Institution, the late Sir William Preece. In a paper * published in 1885 he described some experiments that had been made on what is known as the "Edison effect." Edison had found that, under certain conditions, a blue glow appeared inside some of the glow lamps made in his laboratory, and in order to discover the cause of this he inserted inside the globe a plate completely disconnected from the filament. He found that if a galvanometer was connected between the metal plate and the positive end of the filament, a considerable current flowed through it when the blue glow appeared inside the bulb. Preece brought back from America some of these lamps with metal plates inside the bulbs, and performed a number of experiments with them in his laboratory. At the end of his paper he stated that "this Edison effect is due to the formation of an arc between the carbon filament and the metal plate, and this arc is due to the projection of the carbon particles in right lines across the vacuum space." We know now that this explanation is incorrect, and soon afterwards Sir Ambrose (then Professor) Fleming began that important series of researches which led to the development of what is now known as the "Fleming valve." He showed what was really happening inside the bulb containing the heated filament and the metal plate. He laid the foundation on which the future development of the valve was built, and it was he, of course, who first showed that the valve would act as a valve, i.e. would allow current to pass through it in one direction only, even when it was supplied with very high-frequency currents.

There is a good deal to be said for what Lord Rayleigh called "wild catting" in experimental research. The introduction of the third electrode by Lee de Forest was made in this way. It is evident that he had very little understanding of the action of the 3-electrode valve when he first made one. The use of the third electrode was one of the greatest steps in the development of the technique of the thermionic valve, since it was after the insertion of this electrode that it became possible to use the valve as an amplifier and generator of electric waves.

The discovery of the fact that the resistance of selenium is reduced when this element is exposed to light was first applied by Shelford Bidwell in an attempt to transmit pictures, and the photo-electric properties of potassium and potassium-sodium alloys were studied by Elster and Geitel. At a soirée of the Royal Society over 20 years ago, a demonstration was given by Sir Ambrose Fleming of a sodium-potassium photo-electric cell which gave an e.m.f. of nearly 0·5 volt and a current of 5 microamperes. The advantage of the cell as compared with selenium is that it is very nearly instantaneous in its action and gives its current almost immediately a beam of light falls on it. The practical possibilities of these results were obvious, but it has taken nearly 20 years for the "talkie" to emerge, for

† *Ibid.*, 1901, vol. 30, p. 232.

* *Proceedings of the Royal Society*, 1885, vol. 38, p. 219.

it was only after the methods of amplification made possible by the valve had been perfected that the production of the currents from these cells became useful in practice. The "talkie" film makes use of the properties of the photo-electric cell. A trace on the film varies the intensity of a beam of light passing through it, and so produces the current which, when amplified, is sufficiently powerful to operate a loud-speaker. At the present time a number of engineers are engaged on the maintenance of "talkie" equipment, though it is perhaps too much to say that this has led to another new industry.

Television also may become practicable in course of time. That is another application of the same experiment.

Perhaps the most interesting observations made within recent months in wireless telegraphy have been those by Stormer and Hals on wireless echoes of long delay. Stormer has noticed that in some cases an echo of a short-wave signal, with a wavelength of about 30 metres, appeared to return to the sending station as long as 3 minutes after it had been sent out. Many observations of this kind have been made, the time interval ranging from several seconds up to over 4 minutes. A very interesting paper by Pedersen has recently been published,* in which he has discussed the possible explanations of this result. He has shown that it cannot be explained by a signal travelling round and round the earth continuously, for the attenuation of the wave would be too great; neither can it be explained by a lowered group velocity in the space above the Heaviside layer. The theory which meets the facts most successfully is that the wave penetrates the Heaviside layer, impinges on an electrical stream of charged particles emitted by the sun, and is in some way reflected back again to the earth. It is estimated that the length of path necessary to account for the delay in the echoes must be over 75 million kilometres, so that the signal must have traversed nearly a quarter of the distance to the sun before returning once more. The theory is borne out by the fact that these echoes are heard only at times of magnetic storms, when it is known that sun spots are actively sending out streams of charged electrons. The results are of considerable interest from a scientific point of view. If confirmed, they would appear to be the first records of signals sent out from the earth which have penetrated the upper regions of the atmosphere and returned again.

Electrical Engineering Materials.

Such are some of the fundamental scientific discoveries which have proved of importance to the electrical engineering industry; but there are many other sciences which have been of great value to electrical engineers. Some of the most valuable scientific work that has been done within recent years is that on engineering materials. It is, of course, many years since Barrett, Brown and Hadfield first published their researches on silicon iron, and showed how much smaller were the losses in this material when subjected to alternating magnetization than in ordinary iron. It is not too much to say that the discovery of silicon iron enabled as great an advance to be made in the design and construction of transformers as any other single experimental fact. It enabled the designer to reduce the weight of the iron cores of transformers to nearly half the value that would have been needed without it, and simplified the problem of cooling. More recently the discovery of cobalt steel has led to almost as great a revolution in the design of permanent magnets. Before its discovery a coercive force of 60 or 70 with tungsten steel was the greatest that had been possible, and this was a great advance on the figures with iron containing no tungsten; but a coercive force of nearly 250, such as is now possible with a steel containing 20 or 30 per cent of cobalt, has enabled permanent magnets to be made of less than one-third the weight previously required. Instead of the heavy horseshoe magnets previously needed in magnetos, it is now possible to use short straight bars 3 in. long and 1½ in. wide, such as no maker of permanent magnets would have attempted to use with materials of lower coercive force. Another alloy which has enabled great developments to be made is the nichrome wire now used so universally in radiators and heaters of all descriptions. In this connection I should like to refer to a series of experiments recently made at Liverpool University by Dr. E. C. Walton on the causes of failure of such substances when used in cookers and boiling-plates. The chief cause of failure is the presence of salt in any solution that may fall on the heated spiral. If such a spiral is immersed in fresh water and heated it will last well, but in the presence of a small quantity of salt electrolysis occurs and the metal corrodes rapidly. Milk also causes the heating element to become heavily coated with a thick hard mass which prevents the radiation of heat and finally causes the failure of the element. Fatty substances which do not contain salt have very little effect on the heating element. The effect of electrolytic corrosion with alternating current is very much less than with direct current. With one such wire electrolysis caused breakage after only 20 minutes' immersion in a 1 per cent salt solution when direct current was passed through it, whereas the same wire lasted for nearly 3 hours when alternating current having the same R.M.S. value was used to heat it. In milk the same wire lasted for 1 hour 55 minutes when direct current was passed through it, while with alternating current of the same R.M.S. value the wire showed comparatively little deterioration after 10 hours' immersion. This fact is of interest to central-station engineers who are now changing over their systems from direct to alternating current.

In a paper* by Robert Mallet on the "Action of Water on Iron," he states that alloys containing certain elements, e.g. nickel, cobalt, copper and chromium, are less easily corroded than iron, and that "Michael Faraday had found that alloys of most of the metals with steel which he had tried were much less acted upon by moist air than steel unalloyed." It was, however, a Sheffield man, M. Brearley, who first noticed that iron containing from 11 to 14 per cent of chromium would not rust. This, of course, has an increasing range of application in all kinds of electrical appliances, while chromium plating is becoming as common as nickel plating.

* R. Mallet: *Report of the British Association*, vol. 7, p. 265.

Among materials that have led to great developments in telegraph and telephone transmission, permalloy, discovered some years ago, should be mentioned. This material has a permeability nearly 300 times that of the best soft iron at low flux densities, and has greatly facilitated the loading of underground telegraph and telephone cables. It has recently been used in the form of a thin tape wrapped round the conductor of a 2 000-mile submarine cable. The loading of the cable has diminished the distortion in a manner similar to that in which it is reduced in distortionless telephone cables, and has increased the speed of transmission by more than five times as compared with older types of cable.

DISTRIBUTION NETWORKS.

One of the most important problems before the supply engineer to-day is the economical design of the transmission network. In some cases the cost of the distribution network is four times as much as the cost of the generating plant. The problem is one which requires intensive study, since the cheapening of the cost of electricity depends as much on a reduction in the cost of the distributing network as on any other factor. Here again science and scientific method have been able to render notable service. A most valuable series of researches was undertaken by the Electrical Research Association, the results of which have been published in the *Journal*,[*] with a view to determining the maximum current that can be passed through buried cables without danger to the insulation. This information is now available to the supply industry and will save it many hundreds of thousands of pounds.

In South Africa it is almost universal for the supply systems to remote districts to consist of overhead lines. The distribution network is carried by overhead wires supported on steel or ferro-concrete poles. Provided that care is taken in the placing of these poles their presence is almost unnoticed, and the saving in cost as compared with underground cables is very considerable. The problem of supplying electrical energy to the suburbs of towns like Johannesburg or Cape Town is much more difficult than it is in the case of the more concentrated towns in England; but with the development of the suburban area, with 8 and 12 houses to the acre, which now surround all our big towns, it would seem to be inevitable that the distribution network must be carried overhead unless the cost of electricity is to become prohibitive. For remote districts with very bad load factors it may be possible to use iron wires instead of copper and aluminium. If this is done it is important to have an exact knowledge of the behaviour of the metals which may be used as substitutes. Some figures giving the magnetic and electrical characteristics of such wires, and the chemical composition and treatment that results in the best quality, have recently been published[†] by Dr. Walton, and it is to be hoped that similar results will be available for the other cheap materials, giving the same detailed particulars of the mechanical and chemical properties of the substances to which they relate.

During a visit that I made this summer to South Africa, I was interested to find that the study of lightning and the nature of lightning discharges had been of no small service to the engineers in charge of the recently electrified Natal main line. During the summer the lightning storms in this district are very severe, and when electric traction was first installed the interference with the working by the almost continuous lightning storms threatened to jeopardize the success of the undertaking. The research engineers of the railway, however, made a complete study of the nature of the breakdowns, and have been able to prevent undue interference, thus saving the electrification scheme from failure.

MEASURING AND RECORDING APPARATUS.

Electrical engineering is concerned primarily with the construction of apparatus for the generation and distribution of electrical energy, or with electricity as a means of communication, but, like other applications of physical science, it owes much of its progress to accurate measurement and observation. The devising of instruments and apparatus for indicating and recording purposes has proved of incalculable value to the electrical industry. It was my good fortune to be associated for many years with the late Mr. Duddell, and I venture to think that the practical progress he made with the oscillograph, and the power it gave of observing quantities that were varying very rapidly, has helped the operator and the designer of electrical machinery and apparatus to a very marked degree. It was only after the oscillograph became available that some of the hitherto obscure phenomena in electrical machinery and apparatus were explained. The oscillograph did for electrical machinery very much what the indicator did for the steam engine. More recently the cathode-ray oscillograph has enabled the properties of materials to be investigated at wireless frequencies, and the klydonograph, when calibrated with a Dufour cathode-ray oscillograph, has given much useful information on the nature and intensity of lightning storms. The oscillograph also enabled detailed investigations to be made on Graham Bell's problem, the analysis of vowel sounds, and, with the development of broadcasting and the necessity for an exact reproduction of music and the spoken word, the study of what has been called the "new acoustics" has again become important.

It is impossible to lay too much stress on the necessity for accurate observation of electrical quantities. It was accurate measurement by the late Lord Rayleigh and Sir William Ramsay that led to the discovery of argon and other new gases that are now being used in the construction of gas-filled lamps. The utmost care should be taken to secure accurate results in all observations; it is notable that nearly all great discoveries have been based on effects which are relatively small. Oersted, Faraday and Thomson, to whom references have already been made, would never have observed the phenomena for which they obtained world-wide fame unless they had noticed small and insignificant effects. It is significant that big manufacturing undertakings all over the world have now established research laboratories on a very extensive scale, and that they do not confine their activities to the testing of apparatus and materials used in the factories, but employ many people who are engaged in the study of pure science.

[*] *Journal I.E.E.*, 1921, vol. 59, p. 181; 1923, vol. 61, p. 517; 1926, vol. 64, p. 161.

[†] *Ibid.*, 1928, vol. 66, p. 1065.

H. D. Arnold of the Bell Laboratories may be quoted: "Our research problems are scattered along the whole frontier of the sciences which contribute to our interests, and extend through the fields of physical and organic chemistry, of metallurgy, of magnetism, of electrical conduction, of radiation, of electronics, of acoustics, of phonetics, of optics, of mathematics, of mechanics, and even of physiology, of psychology and of meteorology."

Manufacturers are not necessarily philanthropists: they realize that such study pays.

The universities have done a great deal in the training of men who can staff such laboratories—that is one of their primary functions; and they can best do this part of their work by encouraging their students to carry on investigations themselves. Although a great many of the discoveries that have proved of such importance have been made in university laboratories, many of those that have been described have been made by private investigators. It is of the utmost importance that such studies should be encouraged, and that investigation and discovery should not be hampered by lack of means. Faraday carried out his work for the love of knowledge, and there are to-day many research workers whose chief concern is the pursuit of knowledge for its own sake; but that is no reason why they should not receive adequate material recognition. Scientific discovery is the basis of all electrical engineering: without it the electrical industry would not exist. It is as necessary that it should be encouraged to-day as ever it was, for the discoveries of to-morrow may lead to as great a material revolution as did those of Faraday.

NORTH MIDLAND CENTRE: CHAIRMAN'S ADDRESS

By Thomas Roles, Member.

(Abstract *of Address delivered at* Leeds, *29th October*, 1929.)

In this address I propose to review to some extent the progress which has been made, in matters appertaining to electricity and more particularly to the electricity supply industry, during the period of 15 years which has elapsed since I last addressed you as your chairman. That much of this progress has resulted from the War cannot be denied, as measures that were taken and inventions brought out and developed to assist in the prosecution of the War have in many cases since been utilized for the benefit of mankind under peace conditions; and the greatly increased use during recent years of electricity in various directions and for many purposes has been undoubtedly due in a large measure to the stimulus given during the War period to the invention and perfection of electrical apparatus for military needs.

The position as regards the electricity supply industry in this country in 1914 was, roughly speaking, that some 600 undertakings, company and municipal, were supplying electricity for public purposes, and that the total number of units sold by these concerns was under 2 000 millions per annum. This energy was very largely used for lighting and traction purposes, but electricity was rapidly being adopted in connection with power installations and for heating, chiefly where heat was only intermittently required. Amongst large power users electric driving had found favour in shipyards and such engineering and other works in which the machines to be driven were situated some distance apart, electrical transmission and the individual drive having been demonstrated to be more economical than power transmission by steam or by shafting. In some instances electrical driving had been introduced into textile mills and other similar establishments, but developments in this direction were made with difficulty owing to the conservatism of the majority of the power users, the necessity of quoting extremely low prices for electrical energy in order to secure consumers, and the fact that in many textile mills, particularly those connected with the woollen and worsted industries, a considerable amount of steam was required for process work, and boiler plant could not be dispensed with entirely.

The cheapness of coal also militated against the adoption of electricity for power purposes, as in many cases it was less costly to waste coal in running an uneconomical steam plant than to pay interest and provide for depreciation in respect of capital which would have to be expended on the installation of electrical plant.

The use of electricity for lighting purposes was recovering from the check experienced in the early years of the century when, by the development of the incandescent gas mantle, more especially of the inverted type, brilliant lighting effects could be obtained at much lower cost than by the use of the carbon-filament electric lamp. The competition of the incandescent gas lamp had been met by the introduction of the Nernst lamp, the tantalum lamp, the tungsten lamp, first of the squirted and then of the drawn-wire filament type, and finally by the gas-filled lamp. On the last-named being placed on the market but a year or so prior to the commencement of the War, anxiety was again caused to those responsible for the finance of a number of electricity supply undertakings, the incomes of which depended mainly on their output for lighting purposes, as these undertakings had barely recovered from the losses occasioned as a result of the substitution by their consumers of metal lamps for carbon lamps. It was not generally anticipated that this further reduction in the quantity of electricity required to produce a certain amount of light would be compensated for by the public adopting a higher standard of illumination and by the energy which would be demanded by the many additional consumers who would be obtained owing to the better and cheaper light provided.

There were, however, a number of undertakings which had realized that even on domestic premises there were other uses for electricity than the provision of light, and had framed tariffs designed to encourage the use of electricity for all purposes, and especially for heating and cooking. The electric fire had already become popular in districts in which such tariffs were in operation. The development of the electric cooking range had not proceeded so far as to give satisfaction except to enthusiasts. Electric irons and small pieces of cooking apparatus, in which, as a rule, the heating element was self-contained, were in fairly extensive use.

Early in the year 1915 the urgent call for munitions of war made it necessary that existing factories and workshops capable of producing material for war requirements should be extended and additional premises erected and equipped for this purpose. The problem of obtaining the necessary power to drive the machinery in these enlarged and new factories became a pressing one, as time did not permit of large numbers of boilers and engines being built, the power in many cases being needed immediately. The result was that the Government and firms and persons requiring power were brought face to face with the fact that power stations existed in most districts in the country, and from the majority of these power stations more or less electricity could be obtained which could be utilized for power purposes with but little loss of time.

During the earlier years of the War the chief concern of the authorities was the obtaining of electricity, and the question as to whether such electricity was produced economically or otherwise was but little considered. Later, however, owing to the large quantities of coal which were required to carry out many of the processes in connection with the manufacture of munitions, and the fact that the ranks of the miners were being depleted by reason of enlistment and, finally, conscription, economy in the use of coal in the production of electricity became a vital question. The Board of Trade was made aware of the fact that by a judicious linking up of groups of power stations in the country a considerable saving of coal could be effected, and as a result, in the middle of 1916, the Board issued a memorandum urging electricity supply undertakings to come to arrangements with each other for the linking-up of their respective power stations. A number of committees were formed in different parts of the country for the purpose of giving consideration to the recommendations contained in the memorandum and the means by which such recommendations could be carried out. For various reasons, however, one of the chief of which was the difficulty in obtaining material and apparatus for carrying out the schemes, comparatively little was done during the period of the War on the lines recommended in this and similar reports, but the idea had obtained firm root in Government and other circles, with the result that a Special Sub-Committee, called "The Coal Conservation Sub-Committee of the Reconstruction Committee," was appointed by the Minister of Reconstruction to consider the coal problem, and in December 1917 issued an Interim Report on "Electric Power Supply in Great Britain," in which recommendations were made for the reorganization of the system under which electricity was being supplied throughout the country, in order that production should be carried out on more economical lines, with consequent saving in the amount of coal consumed for the purpose. Other committees which were appointed dealt more or less fully with matters relating to the electricity supply industry, and a lengthy report was issued in April 1918 by a Committee appointed by the Board of Trade to consider the question of electric power supply. The conclusions of this Committee, which to a large extent followed the lines of those of the Coal Conservation Sub-Committee as to the conditions governing a cheap supply of electricity, included the following:—

Combined generation within suitable areas; well-situated stations, having regard to condensing water, fuel and distance from consumers; modern and large units of generating plant; uniform standards of system, frequency and pressure as far as now practicable; greater freedom for overhead wires and wayleaves; good technical and business management; adequate and cheap capital.

Having regard to the position of the electricity supply industry under the Rating and Valuation (Apportionment) Act, 1928, it is interesting to note that the Committee's report states that to the above might be added reduced valuations for rating purposes, especially in the case of transmission lines. The economies which might be obtained by the gasification of coal and the recovery of by-products in certain districts were also touched upon.

The report further recommended that a new body, to be called the Electricity Commissioners, should be set up to have, subject to appeal to Parliament in certain cases, general control over the generation and distribution of electricity in the United Kingdom.

Legislation was enacted in 1919 substantially to give effect to the recommendations of this Committee, and the Electricity Commission was thereupon established. Owing, however, to the manner in which, as a result of the opposition of various interests, the original Bill was mutilated in its passage through Parliament, the Electricity Commissioners found themselves unable to carry out to anything like its full extent the scheme underlying the Report of the Board of Trade Committee. In 1922 a further Act was placed on the Statute Book which extended and to some extent modified the 1919 Act, and under the provisions of this and preceding Acts some progress was made. Such progress was, however, in no way commensurate with the exertions of the Electricity Commissioners in the furtherance of the work for which they were appointed, and in their Report of 1925 the Commissioners intimated that they had been striving to supersede small-scale generation in some hundreds of stations, but were compelled by circumstances to sanction the construction of further small power stations and also extensions to power stations which would be shut down eventually.

The Government also being dissatisfied with the progress which was being made in connection with the reorganization of the electricity supply industry in the country, the Minister of Transport appointed a further Committee in 1925 to review the national problem of the supply of electrical energy, and the majority of the proposals of this Committee were embodied in the Electricity (Supply) Bill introduced by the Government in 1926. These proposals differed chiefly from those put forward in previous reports, in that whereas in the latter schemes covering districts were to be carried out by separate authorities set up within such districts, under the Bill of 1926 one authority—the Central Electricity Board—was to be established and made responsible for carrying out approved schemes throughout Great Britain. This Bill, after being considerably amended in its passage through Parliament, was duly enacted, after which no time was lost in the appointment of the Central Electricity Board, and no time has been lost by the Board in proceeding with the work with which it has been entrusted, so that in the near future we should be in a position to judge the results attained and likely to be attained as the outcome of the passing of the Electricity (Supply) Act, 1926.

Although disappointment is often expressed at the tardy progress which has been made in connection with the reorganization of the electricity supply system in this country since the passing of the Electricity (Supply) Act of 1919, I feel it must be conceded that the country has to a considerable extent benefited by the setting up of the Electricity Commission and the work which has been carried out by the Electricity Commissioners, as, speaking generally, since their appointment far greater attention has been paid to economy in connection with the generation of electricity by those responsible for the operation of electricity supply undertakings than was previously the case. The fact that it was generally known that under the various schemes put forward it was intended wherever possible to shut down the smaller generating stations and transfer their loads to the larger stations has stimulated electrical development, in that it has caused those responsible for the management of small stations to make strenuous efforts in the direction of finding load with a view to justifying their stations being enlarged to such a size that they could be retained in use in connection with any schemes which might be put forward for their districts. The fact also that economy in coal consumption would have a considerable bearing on the extent to which a station would be utilized in the future, and that particulars of the thermal efficiency and fuel consumption of all public generating stations are set forth in a report issued yearly by the Electricity Commissioners, has caused station engineers throughout the country to vie with each other in the production of electricity with the smallest possible consumption of fuel. The outcome of this has been that the average consumption of fuel per unit generated has greatly decreased.

As an indication of the saving in fuel which has been effected in the generation of electricity during the past nine years for which the Electricity Commissioners have issued their annual reports of analyses and summaries of the returns of fuel consumption and units generated made to them by authorized undertakers, railway and tramway authorities, and certain non-statutory undertakings, I would mention that in the report issued for the year ended 31st March, 1921, the total units generated in stations consuming coal or coke is given as 4 955 514 403, and the average consumption of coal per unit generated was 3·32 lb. The report recently issued for the year ended 31st March, 1929, shows that the number of units generated in steam stations using coal, coke or oil-fired boilers was 10 377 107 062, and the average consumption of fuel per unit generated (converted to a coal basis) was 2·05 lb. From this it will be observed that in this period of 8 years the amount of coal consumed per unit generated has fallen from an average of 3·32 lb. to 2·05 lb., representing a saving of 1·27 lb. Had the 10 377 107 062 units generated in steam stations, as given in the latest report of the Electricity Commissioners, involved the consumption of the average figure of 3·32 lb. of coal per unit generated, as in 1921, the consumption of fuel (converted to a coal basis) would have been 15 399 868 tons, as against the actual consumption of 9 516 419 tons, which shows that a saving of no less than 5 883 449 tons has been effected.

It may thus now be fairly claimed that, quite apart from any advantages which will be gained as a result of the Central Electricity Board's operations, the attainment of the position stated to be desirable in the report of the Coal Conservation Sub-Committee is well on the way to being accomplished.

Much has been said on the subject of Government interference with the electricity supply industry, which interference is stated by many to have retarded rather than encouraged progress. While sympathizing with many of the views put forward in this connection I think we may take it that, on the whole, the interest displayed by successive Governments in our industry has been productive of beneficial results, as the fact that the provision of an ample and cheap supply of electricity throughout the country has been made a plank in the platform of each of the political parties cannot fail to have had considerable advertising value, and the public demand for electricity has thereby been greatly stimulated.

Having reviewed the developments which have taken place in connection with the organization and control of the electricity supply industry during the past 15 years, it may prove of some interest if I touch upon the progress which has been made by the industry from a more technical aspect, more especially in relation to steam-electric generating plant.

To afford supplies of electricity required in the days immediately prior to the outbreak of War the larger power stations had for the most part been equipped with turbo-alternators, and in the smaller power stations it was becoming the practice to install machinery of this type. Many undertakings were, however, supplying the whole of their consumers with electrical energy in the form of direct current, even though in some of these cases the electricity was generated as 3-phase alternating current.

The usual steam conditions then obtaining in power stations in this country were pressures of from 160 to 200 lb. per sq. in. gauge and temperatures of from 450° to 550° F. There were, however, power plants on the Continent working at considerably higher steam temperatures than those usually adopted in this country, one plant operating with steam at 660° F. In some large power stations boilers having an evaporative capacity up to 40 000 lb. per hour were in use, and boiler-house efficiencies of from 65 to 75 per cent were attained.

As typical of turbo-alternators of the largest capacity in commission in 1914, mention may be made of the 15 000-kW 3-phase set, running at a speed of 1 000 r.p.m., installed in the Stuart Street station of the Manchester Corporation. This set had an overload capacity of 19 000 kW for a period of 30 minutes at a power factor of 0·95. The steam conditions at the turbine stop-valve were 190 lb. per sq. in., 530° F., and the vacuum was 27½ inches. The steam consumption at a load of 15 000 kW was 13·65 lb. per kWh.

At this period a good steam plant could attain a thermal efficiency of about 15 per cent.

Up to 1914 there were no turbo-alternators of 5 000 kW or over in this country running at a speed of 3 000 r.p.m., although at least one set of 5 000 kW capacity designed for this speed was at work on the Continent. In December, 1915, however, a turbo-alternator of 6 250 kW capacity built to run at this speed was started up in the Stuart Street station at Manchester.

Although 15 000-kW sets were considered large on this side of the Atlantic, the erection of 30 000- and 35 000-kW single-shaft machines was commenced by the Philadelphia Electric Co. in the United States towards the end of 1914. The steam conditions for the 35 000-kW set were 215 lb. per sq. in. pressure and 540° F. total temperature, the steam consumption being approximately 12·0 lb. per kWh. Had there been the demand for such large units of plant over here no doubt it would have been met by British manufacturers, seeing that in 1912 a 25 000-kW turbo-alternator was being built in England for the Commonwealth Edison Co. of Chicago.

The first radical departure in this country from the steam conditions which had been generally adopted was the installation during the year 1915 at the power station of the British Thomson-Houston Co., Ltd., Rugby, of steam-raising plant and a turbo-alternator designed for a steam pressure of 375 lb. per sq. in. and a temperature of 700° F.

In 1918 a 45 000-kW turbo-alternator was put into operation at the Connors Creek power station of the Detroit Edison Co., U.S.A. A notable feature of this set was that its generating pressure of 12 200 volts was stepped up to 24 000 volts by a single 3-phase transformer, the largest of its kind in use at that time. This power station had achieved what was up to this period the world's record for thermal efficiency, a figure of 17 per cent being attained with an annual output of approximately 210 million units, a maximum demand of 50 000 kW, and a load factor of 47·8 per cent. In this country the highest thermal efficiency reached up to that time was 16 per cent.

The year 1918 also saw 12 boilers each having an evaporative capacity of 50 000 lb. per hour installed in the Rotherham power station, these boilers being stated to be the largest up to then constructed in this country.

During the following year boilers of 91 000–104 000 lb. per hour evaporative capacity were installed in the Stuart Street station, Manchester, the steam pressure being 225 lb. per sq. in.

In the year 1920 the North Tees power station was started up, the first installation of steam-raising plant in which comprised 10 boilers each having an evaporative capacity of 42 000 lb. per hour, operating at a steam pressure of 475 lb. per sq. in. and a total temperature of 700° F. In this station re-heating was adopted, as were also the extraction of steam from the main turbines for feed-water heating and the preheating of air to the furnaces. The turbo-alternators installed were each of 20 000 kW capacity, designed for a speed of 2 400 r.p.m.

In spite of the notable increase in steam pressure at the North Tees station and the introduction of such refinements as re-heating, the general tendency in connection with power-station design was still to keep to more moderate steam conditions, as is instanced by the Dalmarnock power station of the Glasgow Corporation, which was started up at about the same time as that at North Tees. For the Dalmarnock station the steam pressure adopted was 275 lb. per sq. in., with a total temperature of 700° F. The first boilers to be installed in this station each had an evaporative capacity of 62 000 lb. per hour, and the turbo-alternators each had an output of 15 000–18 750 kW. The steam consumption of these generating units was 10 lb. per kWh, with a vacuum of 29·1 inches.

In 1921 a 30 000-kW set—then the largest in the country—was installed in the Rotherham power station. This machine, which was constructed to operate under steam conditions of 200 lb. per sq. in., a total temperature of 588° F., and 28½ inches of vacuum, was of the single-cylinder type running at a speed of 1 500 r.p.m. The steam consumption of this machine was 11·1 lb. per kWh.

By this time boiler-house efficiencies of about 80 per cent had been recorded and steam installations for pressures of 250 lb. per sq. in. had become common, and a number were either at work or under erection to operate at a pressure of 350 lb. per sq. in. Greater developments in connection with the increase of steam pressures were, however, being made by American engineers, and a number of stations were constructed in the States in which the steam plant was designed to operate at pressures of from 500 to 600 lb. per sq. in., and in 1925 the Edgar station of the Edison Electric Illuminating Co. of Boston, in which steam plant to work at 1 200 lb. per sq. in. was installed, commenced to operate. Since then other plants have been built in the United States to work at still higher steam pressures, and it is reported that two boilers will shortly be put into use in that country to produce steam at a pressure of 1 840 lb. gauge.

At the present time there is still no power station belonging to a public electricity supply undertaking in Great Britain which has boilers working at a higher pressure than those at the North Tees station, and until very recently no other boilers in this country were operated at so high a steam pressure. During this year, however, several very large boilers designed to work at a pressure of 800 lb. per sq. in. have been erected and put into commission by the Synthetic Ammonia and Nitrates, Ltd., at Billingham-on-Tees. A boiler and turbo-alternator constructed to operate at a pressure of 1 100 lb. per sq. in. gauge will shortly be put to work at Bradford, and statements have been made to the effect that a large manufacturing concern in the South of England intends to install boilers for working at a pressure of something over 1 800 lb. per sq. in.

With regard to the size of turbo-alternators, sets are now being built in this country to operate at a speed of 3 000 r.p.m., having a capacity of 30 000 kW at 0·8 power factor, and sets of 67 250 kW capacity to run at 1 500 r.p.m. are on order for the new Battersea station of the London Power Co.

In the United States of America very much larger machines are at work, one at the Hell Gate station of the New York Edison Co. being of 160 000 kW capacity, and another built for the State Line Co. of Indiana being of 208 000 kW capacity.

As indicating the progress which has been made in the direction of increasing the thermal efficiency of British steam-operated power stations, the recently issued report of the Electricity Commissioners shows six stations as having thermal efficiencies exceeding 20 per cent, the highest figure recorded being 21·35 per cent.

Much could be said with respect to developments in connection with plant and apparatus for the control, transmission, conversion, transformation, distribution and utilization of electricity, and also as regards progress in other branches of the electrical industry, as, for example, wireless telegraphy, wireless telephony and television, which since pre-War days has been most remarkable. Time, however, does not permit of these matters being even touched upon.

As members of the Institution we may feel proud of the part which has been taken by our Institution as a whole and by its members individually during the period covered by this retrospect. Its assistance and that of its most prominent members was time and again sought by the Government during the War, and has since often been solicited to afford help in the work of reconstruction. As a result the importance and influence of the Institution have become greater each successive year.

Great credit must be given to the Presidents, Members of Council and others who have played leading parts in connection with the Institution's wonderful development in recent years.

Through the medium of the Centres and Sub-Centres established in different parts of this and certain other countries the Council has been kept in touch with the needs and desires of all British members of the electrical industry, and has wisely made arrangements as a result of which the majority of the sections into which the industry is divided have found it more desirable that their personnels should enter into membership of the Institution rather than that separate societies should be formed in their interests. A Meter and Instrument Section, a Wireless Section and a number of Student Sections have thus been established.

The membership of the Institution, which was 7 045 in 1914, has now risen to 13 561, and the annual income from subscriptions from £15 454 to £34 693, and an examination of the Balance Sheet published in the *Journal* in July last will show the remarkable soundness of the financial position of the Institution at the present time.

We present members have in our Institution a goodly heritage, and it should be the endeavour of each one of us to do everything possible to increase the Institution's prestige and its usefulness to the industry, our country and the world at large, so that on our passing we may leave to those who follow a society which can, to a still greater extent, contribute to the good of its members and mankind in general.

SCOTTISH CENTRE: CHAIRMAN'S ADDRESS

By GEORGE MORGAN, Member.

(*Address delivered at* GLASGOW, 12*th November*, 1929.)

During the past few months the electrical resources of this city have been augmented by the completion and setting to work of the new refuse destructor works belonging to the Cleansing Department of the Corporation of the City of Glasgow. Since installations of this type are relatively rare in this country, and as the present example is probably unique, not only in point of magnitude but also in regard to coherency of design and completeness of detail, I have considered that some description of the methods by which the communal waste is turned to good account and the energy latent therein converted to the form most suited to modern industrial requirements, would prove of interest.

The inception of the present project dates back to the year 1912, when investigations were commenced with regard to the provision of refuse disposal works for the southern area of the city. The outbreak of hostilities in Europe naturally delayed the completion of this part of the work, and it was not until the year 1922 that the decision was finally made to undertake the installation of plant having for its principal object the generation of electricity from the city refuse.

The site ultimately chosen lies in the south-western quarter of the city, where the process of natural expansion is both rapid and certain. It extends to an area of some 15 acres, and is bounded on its southern side by the main railway line and on the east and west by main roads which tap the densely populated districts surrounding the shipbuilding yards and give ready access to the new arterial roads leading to new housing areas of the city. On the northern side, land for extension of the works is available when required.

Whilst, as I have already indicated, the main purpose of the plant is directed towards the generation of electrical energy, it will be readily appreciated that a heterogeneous collection of material, as represented by household and industrial refuse, contains many substances the value of which varies in accordance with the method of disposal. Realization of this fact has led, in the present instance, to the combination, as conveniently and economically as possible, of the functions of a modern salvage and destructor plant with those of an equally modern electricity generating station. The chief consideration with regard to the refuse is naturally that concerning its value as a fuel. It follows, therefore, that it must receive careful preparation, and all substances which are incombustible, or which are inherently valuable as scrap, must be removed in the initial stages, and the remainder treated in such a manner as to render its combustion a hygienic, reliable and economic process. Not the least of the many peculiarities possessed by a fuel of this nature is its liability to spontaneous combustion. In consequence, storage for a period longer than about 24 hours is undesirable, and the process of collection, treatment and combustion must proceed at a steady pace and in accordance with the exigencies of the electrical load on the station. Fortunately, the system into which this electrical output is delivered is a large one, and means are available whereby the load factor of the station may be kept high.

In order that the various functions which have been indicated may be properly accomplished, the works are divided into three main sections, each with its own separate building. These are, respectively, the reception and screening house, the incinerator and boiler house, and the generator house. Appropriate to each of these main divisions, subsidiary plant has been provided for such purposes as (1) the de-tinning of light containers, and their subsequent conveyance with other sheet-metal articles; (2) the crushing and grading of the clinker for road-making, sewage filter beds, racing tracks, and similar purposes; (3) the manufacture of concrete paving slabs, kerbs and steps; and (4) the utilization of flue dust in the manufacture of external finishes for stonework and rough-cast buildings. These few instances will, it is believed, prove to be but the forerunners of many other by-product plants concerned with the fuller utilization of the refuse and all that it contains.

It is, however, from the electrical engineer's point of view that I wish to present my brief review of the destructor works, and from this standpoint I believe that the simplest and most satisfactory way of forming a clear idea of the principles involved and the plant entailed, is to trace the course of the refuse from the moment it arrives until the energy it contains makes its exit through the outgoing e.h.t. feeders.

The crude refuse from the surrounding areas is collected and conveyed to the works in special electric trucks of which I shall have more to say later. These, after traversing a concrete ramp, about 450 ft. in length and with a gradient of approximately 1 in 15, arrive on the first or tipping floor of the screening house, into which are sunk four large rectangular hoppers with their upper edges flush with the floor-level. The contents of each truck, an average of some 5 tons in weight, are then tipped directly into these hoppers. The usual practice in such matters is here departed from inasmuch as, in order to achieve a particularly low loading line for these trucks, self-tipping gear has been excluded from the design, its place being taken by electrically operated overhead blocks. The tank body of each truck is arranged to hinge from either side, and by means of the overhead tackle it can be rotated on this hinge in such a manner as to discharge its contents into the receptacle provided, after which the truck proceeds down a corresponding exit ramp, and out upon another round of its district. These receiving hoppers are each fitted with low-speed apron conveyors which form the floor of the receptacle and gradually carry the contents towards the chute leading to the revolving screening drums, of which there are four, one to each hopper. Any large objects, such as baths, bedsteads, bicycles, etc., are here removed, and the remainder is allowed to pass on. In the initial stages the smaller particles are sifted out through the 3-in. holes in the screens, and the tailings pass on, to be dealt with by the magnetic separators, which remove all loose iron and steel articles and direct them down chutes for further treatment. Tinned articles in good condition are sorted out and sent by telpher conveyors to the de-tinning plant, whilst others not considered suitable for, or worthy of, this treatment are dispatched direct to the baling presses, there to be joined by those which have been de-tinned. The presses, of which there are two, are driven by electric motors and exercise a pressure of rather more than ½ ton per sq. in., producing a compact block measuring 1 ft. square by 1½ ft. in length. The remainder of the tailings fall into pulverizers of the swinging hammer type driven by motors of the high-torque type. These reduce the refuse to particles of approximately the same size as those which have passed through the screens, and render the whole mass much more homogeneous in nature. All subsequent operations, such as handling and firing, are thereby rendered much easier, besides enabling a certain amount of control to be obtained over the nature of the clinker formed in the furnaces.

Manual supervision is retained at all stages in the grading process. Dangerous or bulky articles are either removed or assisted on their way, and finally the initial screenings and the product of the pulverizers unite on the main conveyors, which are situated in pits formed in the ground floor of the screening house. These conveyors, in common with those which carry the screenings or deal with the tailings, are of the trough or belt type. The belt is of rubberized canvas, running on a system of rollers spaced at frequent intervals and arranged to give it a concave surface. The main conveyors, of which there are two, extend for a distance of rather more than 400 ft., and are housed in a covered corridor carried on gantries and rising gradually to a height of approximately 60 ft., where they terminate in a tower erected at the southern end of the incinerator house. At this point the refuse, which must now be regarded as fuel, is transferred to distributors of similar character which again feed shuttle conveyors. These latter are arranged directly over the furnace silos and are traversed on rails to the required position. The direction of motion can also be reversed, so that the fuel may be deposited in any one of the bunkers. As might be expected, the whole of this somewhat elaborate conveyor system is electrically driven, and on account of the extreme importance of its function a complete system of alternative working routes has been established, with push-button control at all vital points. An ingenious system of electrical interlocks prevents the possibility of errors of operation and reduces to a minimum the supervision which would otherwise be necessary.

The problem of firing boilers with such a relatively variable fuel as city refuse is likely to be, is no mean one. The calorific value may vary over wide limits, as may also the moisture content. These depend largely on the season of the year and the climatic conditions existing at the time. In the present instance, the calorific value is of the order of 4 000 B.Th.U. per lb., and the moisture content about 25 per cent. It has also to be remembered that mere combustion of the fuel is not the only problem to be solved. The clinker which is formed is a valuable by-product, and the solution must include means whereby this can be satisfactorily produced both as regards quality and quantity. Many attempts have been made in the past to meet these demands, and the present firing equipment merits description on account of its ingenuity and good general performance. Each of the silos already mentioned is in the form of an inverted cone, of such general proportions that packing of the fuel does not occur. At the lower end is fitted the transfer hopper. This can best be described as a drawer without a bottom, capable of motion to and fro in a horizontal plane. At its inmost position it is filled by gravity from the silos above. When occasion demands, it is drawn forward by the action of a hydraulic ram, conveying its contents towards the opening into the furnace cells below, at the same time closing the exit from the silo by means of a sliding shutter equipped with a shearing edge. On arrival over the furnace the contents are deposited on to the grate below, and the hopper is returned to its original position, during which process a firebrick-lined door is restored to its normal place over the furnace inlet opening. The furnace grates are themselves of a special type and are arranged to oscillate to and fro in accordance with the requirements of the fuel and the formation of a satisfactory clinker. These are two in number and are placed one above the other. The fresh charge on the upper grate is ignited by the incandescent clinkers which have been deposited on the auxiliary grate beneath, and after the lapse of a certain length of time, during which one or more charges have been thoroughly consumed, this grate is caused to move backwards towards the rear of the furnace, removing, by means of scrapers depending from its front edge, the partially cooled clinkers on the grate beneath, simultaneously depositing its own load in their place. The cycle is completed by a forward traverse of the upper grate, which permits the hinged scrapers already mentioned to act as spreaders, causing the new clinkers to be distributed evenly over the surface of the lower grate and in a position to ignite a fresh charge deposited on the grate above. There are five such cells or furnaces in each unit, each capable of dealing with about 10 cwt. per charge and two charges per hour, that is, 5 tons per unit per hour. The total equipment of the incinerator house is 8 units, or 40 cells in all.

The clinker, which amounts to about 30 per cent of the weight of fuel burnt and is cleared off the auxiliary grate in the manner already described, falls down a chute into the hopper provided for it. Small storage-battery locomotives, running in tunnels beneath the firing floor, periodically remove the clinker in self-tipping trucks and convey it to the quenching pits situated outside the incinerator house, adjacent to the railway sidings and clinker-crushing and -grading plant. Grab and telpher equipment is utilized in removing the quenched clinkers to either of these points, while a bucket-type conveyor disposes of the sludge direct into railway trucks or as otherwise required.

The products of combustion from each unit are led through a common combustion chamber to a boiler of the water-tube type and thence to one of four stacks—one stack to each pair of boilers. Forced draught is provided to each cell, and all the grate-operating gear, which is hydraulic, is provided with interlocking controls so that draught is cut off when the furnace doors are opened or the transfer hoppers are in operation. Careful firing and adjustment of the forced-draught pressure, in conjunction with the natural draught provided by the stacks, enables approximately balanced conditions to be obtained. Owing to the nature of the fuel, 1½ per cent of dust is carried over into the combustion chamber and its removal during the period of operation has proved rather a problem. A system of double doors has been devised which will, it is hoped, successfully circumvent this difficulty.

In recognition of one of the functions of the refuse works, the combustion chambers are adapted for the disposal of large carcases. Suitable doors are provided, both in the roof of this chamber and at the floor-level, while mechanical lifting gear eliminates the necessity for any manual handling.

The boilers are of the cross marine type and are fitted with superheaters, feed-water regulators and soot blowers. The nominal capacity of each boiler is 22 000 lb. of steam per hour at a pressure of 200 lb. per sq. in. (gauge) and final temperature of 650° F. It has been recognized that circumstances may arise in which alternative firing arrangements may be required, and, in view of this, four of the boilers are provided with additional furnaces designed for the use of coal as fuel. These, however, are regarded in the light of emergency gear and are hand-fired.

One of the most notable features of that part of the installation so far described is the general cleanliness which prevails in the various departments. This is in marked contrast to what might reasonably be expected when the nature of the fuel substance is taken into account, and has been achieved by the employment of mechanical handling gear of the most careful design at all stages in place of the manual labour more usually met with in such establishments. The same thorough attention to points of detail is again accorded the refuse from the technical point of view. From the moment it is tipped into the receiving hoppers it is regarded as a potential fuel and every reasonable precaution has been adopted to ensure that continuity of flow throughout the system which its nature and the purposes of the complete installation demand. At each stage in its progress an endeavour has been made to conserve, and ultimately to utilize in the highest degree, the calorific qualities of the refuse—the design and operation of the furnace units is a case in point—with the result that on an average 2·5 lb. of steam is obtained for each 1 lb. of refuse consumed. This represents a combined boiler and furnace efficiency of about 75 per cent, at the pressure and temperature concerned, and must be regarded as distinctly good for plant of this nature. The total capacity of this part of the complete installation is 640 tons of refuse per 24 hours, but the present normal rate of electrical output demands only 480 tons to be dealt with in this period. A margin of 33 per cent of plant is therefore available to cope with any breakdown which may occur.

Having now described in some detail the manner in which the heat energy latent in such unpromising material as city refuse is transferred into steam at 200 lb. per sq. in. and at 650° F. total temperature, I shall proceed to that part of the installation which is more familiar to the average electrical engineer, namely, the generating station. This building is entirely separate from, but adjacent to, the incinerator house. The general design is in consonance with present-day practice in such matters. A two-level arrangement has been adopted for the plant installed, the turbo-alternators and their control gear being on the first floor, while all auxiliary plant, such as the condensers with their associated circulating and extraction pumps, are accommodated on the ground-level. Moreover, the main units are placed transversely to the length of the building, with the steam end towards the wall adjacent to the incinerator house. This lay-out allows a simple and convenient arrangement of the main steam piping, and permits the electrical output from the alternators being taken by a short and direct route to the e.h.t. switchboard, which is housed in an annex to the generator house.

The turbo-alternators, of which there are two, are of the well-known high-pressure direct-coupled type and run at 3 000 r.p m. Each is capable of supplying 5 000 kW of 3-phase energy at 0·8 power factor at a pressure of 6 500 volts between phases. The frequency is 50 cycles per sec. and is, therefore, in accordance with the standard chosen by the Electricity Commissioners for the unification of supplies in Great Britain.

The turbines are of the impulse type and are representative of modern land turbine practice. The usual governor-controlled oil-operated valve gear is fitted, and permits an overload of 25 per cent to be carried automatically. Remote control of the speed is provided from the main generator panel on the e.h.t. switchboard.

Following what is now general practice in such matters, the condenser, which is of the surface type, is suspended directly from the exhaust casing of the turbine, part of the weight being taken on powerful helical springs placed below it. As a result of this method, trouble due to the differential expansion of parts at unequal temperatures is avoided. This principle extends also to all pipe lines connected to the condenser, copper expansion pieces being fitted in these. The initial vacuum is obtained by the use of an ejector type of air pump, while the extraction pumps are of the high-speed centrifugal opposed impeller type and are interconnected so that they may be used alternatively with either of the condensers. The absence of a natural supply of water for condensing purposes has necessitated the provision of cooling towers. These are of the usual wooden-chimney natural-draught type, and are capable of dealing with some 700 000 gallons of water per hour, from 93° F. to 75° F., under normal atmospheric conditions. Motor-driven centrifugal pumps, one for each of the condensers, deal with all the circulating water required, not only for condensing purposes but also for the cooling of all oil and air supplies demanded throughout the station. The water required to make good the losses through evaporation, etc., is drawn from the city supply mains. In pursuance of the general scheme for alternative working, these pumps may be interconnected to either of the condenser circulating-water systems as necessity arises.

The alternators have a maximum continuous rating of 6 250 kVA. They present no unusual features in design, being of the modern high-speed type with a non-salient rotor. A closed-circuit system of axial ventilation has been adopted, the air being circulated by means of fans attached to the rotor shaft. Short air conduits, formed in the foundation plinth, convey the exhaust air to a surface type of air cooler through which water, drawn from the main circulating system, is passed. This type of ventilation has several features to recommend it in the present circumstances. A direct-coupled exciter furnishes the current to the rotor winding, voltage regulation of the main machine being controlled by variation of the field current of the exciter at the main control panel on the generator switchboard. In order to minimize the extent of the damage which would ensue as the result of an internal fault developing in the windings, an emergency breaker of the pedestal type is included in the main rotor circuit and can be opened directly from its position beside the steam controls or remotely from the generator control panel. The electrical output from the alternator is taken by a short and direct path to the main 6 500-volt, 50-cycle switchboard. This gear is located on the same level as the turbine-house floor, but in an annex to it.

The switchgear is of the well-known metal-clad, compound-filled type. Its salient features lie in the fact that it is compact and that all live conductors and other parts are enclosed in a continuous metal casing, which is itself directly connected to earth. The horizontal draw-out principle, on which the whole design is based, greatly facilitates the removal from the live busbars of any one of the oil-immersed circuit breakers, either for overhaul or to ensure the absolute safety of workmen on the circuit which it controls. A notable feature of the apparatus is the very complete system of mechanical and electrical interlocks, which practically preclude the possibility of incorrect operation.

The switchboard itself consists of 9 panels or circuit breakers, viz.: 2 for the main alternators, 2 for the 6 500-volt side of the step-up transformer units, 4 controlling the circuits for the works step-down transformers, and 1 busbar sectioning unit, situated between the two main generator switches. Of these, the first four are electrically operated by remote control from the main control and instrument panels. The remainder are manually operated at the circuit breaker itself. All the circuit breakers, with the exception of the busbar sectioning unit, are equipped with electrical tripping gear connected to the particular type of protective system employed for the apparatus which it controls. Thus the main alternators and step-up transformers are provided with circulating-current protection, as are also the three works transformers, while the remaining circuit, which supplies the works garage, is equipped with overload and leakage protection.

With the exception of that which is required for works use, the generated energy is exported to the Glasgow Corporation Electricity Department at a pressure of 20 000 volts and a frequency of 50 cycles per sec. The switchgear for the control of this output is situated at the other end of the control-room annex and on the same level as that already described. Its general construction is similar, but it is designed for a pressure of 20 000 volts and comprises 6 panels—2 for the high-pressure side of the main step-up transformers, with a section switch between them, and 3 feeder switches. The transformer circuit-breakers are included in the circulating-current protective system already mentioned, while the three latter switches are of the special type used in conjunction with the split-conductor protection which has been adopted for the outgoing feeders.

The works substation is located on the ground floor of the switch-house annex, beneath the control-room floor. It comprises three 6 500/440-volt 500-kVA works transformers, two 6 500/20 000-volt step-up output transformer banks of 5 625 kVA each, along with a 440-volt metal-clad switchboard of the same general type as those already described, and a 60-kW 250-volt d.c. motor-generator set. The last named is utilized mainly for the supply of excitation current to the magnetic separators fitted to the screening plant and for the turbine-house overhead crane, but a number of smaller items are dependent on this source for their supply. These include the station lighting and ventilation systems and an auxiliary drainage pump. At week-ends or during the periods when the station is shut down, a stand-by supply at 250 volts (d.c.) from the Electricity Department's network is available at the d.c. switchboard.

In contradistinction to the normal electricity generating station depending on coal for its source of energy, a relatively large amount of power is used internally. This amounts to approximately 1 500 kVA, part of which is used for the manufacturing sections, such as the clinker-crushing and -grading machinery, the concrete-slab plant, and so on. The major portion of the demand is, however, made in conjunction with the fuel-preparation and conveyor gear.

The difficulties attending the storage of prepared fuel have already been touched upon and it will be readily appreciated that the successful functioning of an undertaking of the present description depends wholly upon a regular and adequate supply of fuel material at the lowest possible costs for transport. These onerous duties have been delegated to an extensive fleet of electric vehicles which have been specially designed for the work they have to do. The vehicle garage, which is situated in the south-west quarter of the site and adjacent to the exit ramp from the screening house, has accommodation for upwards of 50 large trucks and is complete with inspection pits, repair bays and offices. The chief feature of interest, however, lies in the electrical equipment for charging the vehicle batteries. Energy for this purpose is delivered at 6 500 volts from the main station busbars, and is reduced to 440 volts in a

3-phase 500-kVA transformer situated in the garage substation, which is equipped with low-tension switchgear of the same pattern as that in the works substation. Immediately adjoining this section is the motor-generator room, which contains also the switchboards and charging panels. Two motor-generators, each of 150 kW output, are installed. These consist of a squirrel-cage motor, with an oil-immersed auto-transformer startor, direct-coupled to a shunt-wound d.c. generator. The nominal pressure at the charging busbars is 120 volts, but means are provided for varying this pressure in accordance with the exigencies of the vehicle batteries on charge, thereby minimizing the energy which need be dissipated in the charging rheostats. The output from these sets is controlled on two d.c. generator panels placed in the centre of the complete switchboard.

On either side of the generator panels are the charging panels. These are of the unit type and are arranged symmetrically in columns and rows, so as to present a uniform appearance. Each charging-panel unit is complete in itself and can be removed without disturbing those surrounding it. The rheostat is interlocked with the circuit breaker, so that improper operation is rendered impossible. Moreover, the breaker is held closed magnetically so that the operation of putting a battery on charge and adjusting the current must be performed simultaneously. In the event of the circuit being broken at any point, the circuit breaker automatically opens, and it cannot be closed until the rheostat has been returned to the zero position. A further feature lies in the provision of a small pilot lamp which indicates that a battery has been connected to the charging circuit and is awaiting attention.

With storage batteries in general, and particularly in the case of those on constant and often heavy duty on vehicles, it is essential that accurate and continuous records of performance should be kept. With this end in view, each charging circuit is provided with an integrating ampere-hour meter to measure the total input of the battery. Such records, in conjunction with others of voltage and acid density, enable faulty cells to be quickly detected and, if necessary, removed for special attention. The charging current in each circuit, and its voltage, are indicated on centrally disposed instruments which can be connected to the circuit in question by operating a self-restoring switch on the appropriate panel. By means of these various devices, the charging process of all the vehicle batteries can be kept under continuous surveillance and a high degree of efficiency achieved.

In the garage a stand is provided for 48 vehicles, to which overhead supply cables are run on insulators. These cables terminate in vertical drops, conveniently placed to the charging-plug position on each vehicle. Means are also provided whereby they may be slung up out of the way when not in use, thus leaving the floor space unobstructed so far as the movement of the vehicles is concerned.

Of the vehicles, upon the successful behaviour of which so much depends, a few words of description may not be out of place. They are of uniform design and have a full-load capacity of 5 tons. A remarkably low loading level has been achieved, thus minimizing the labour entailed in packing the refuse into the tank. The steering lock has also received special attention, in order that manœuvring in confined situations may be facilitated.

The electrical equipment consists of a 40-cell battery of 522 ampere-hour capacity, placed in an accessible position immediately to the rear of the totally-enclosed driving cabin. This renders its removal when necessary a simple matter and also provides an ease of inspection that is reflected in a longer and more satisfactory life than might otherwise be the case.

The total weight of the battery is 1·85 tons, out of a gross laden weight of about 11 tons. The driving motor is nominally rated at 12 h.p., and is, of course, of the series-wound type, while the transmission gear follows automobile practice in so far as it consists of a cardan shaft, with a worm-driven differential gear on the rear wheels.

Neither clutch nor gear box is necessary in this type of vehicle, the required variations in speed, including reverse motion, being obtained by electrical methods. In practice, a speed of 12 m.p.h. on the level is obtained with a full load of 5 tons. In the course of their duties a mileage of about 40 is attained per charge, and this can be considerably extended by judicious boosting charges during the meal interval.

Not the least of the many advantages of these vehicles is their almost total silence of running. This feature is the more acceptable in that their excursions into residential areas are mainly nocturnal in character. As already indicated, the vehicles form the alpha and omega of a description which is of necessity somewhat general in character but, it is hoped, not the less interesting on that account.

From a broad standpoint, the most interesting feature of the whole installation is, I consider, the manner in which the refuse is constrained to accomplish its own destruction and at the same time liberate for other industrial purposes the major portion of the energy which it contains. All this work is done in a manner which, from the point of view of hygiene and economy, could scarcely be approached were it not for the fact that electrical methods have been applied at each step in the process. The whole installation provides but another instance of the manner in which mankind is destined to benefit when electricity, the highest known form of energy, is called upon to execute, on its behalf, any of its multitudinous tasks, menial or otherwise.

EAST MIDLAND SUB-CENTRE: CHAIRMAN'S ADDRESS

By A. D. PHILLIPS, Member.

(*Address delivered at* LOUGHBOROUGH, 8*th October*, 1929.)

In this address I propose to consider—very shortly and perhaps more from the commercial than from the technical point of view—some of the questions relating to the public supply of electricity.

The subject, apart from being more specialized than is generally appreciated, is a fairly wide one. I therefore propose to limit my remarks more particularly to the development of the type of area which has been brought somewhat prominently to the notice of the public during the last year or two, namely, the rural type of area.

The provision of an efficient and cheap supply of electricity is generally admitted to be of the first importance to the development of rural industries and the improvement of the amenities of the countryside. One of the first considerations, however, is as to whether and to what extent a rural supply can be made self-supporting. It has been found by experience that it is possible to do so in quite a large number of instances, provided the all-in cost of making the service available is kept at a minimum.

I do not wish to enter into a discussion on points of political significance, but I think I may postulate that the employment of capital not only does, but should, involve a proper charge payable by the person or persons making use of it or obtaining service from it. The electrical development of rural areas requires quite a substantial expenditure on capital account, and the charges resulting from such expenditure form a material proportion of the cost of rendering such an electrical service available. The only way to keep this proportion within reasonable limits is to see that capital commitments are kept within proper bounds and, further, that expenditure so incurred is employed to the best advantage.

By encouraging the use of overhead distribution lines and by their efforts to overcome the prejudice of local authorities and others against such use, the Electricity Commissioners are performing a valuable service to the community. A good deal, however, still remains to be done. Although the Commissioners have recently revised the code of Overhead Line Regulations, resulting in a quite substantial reduction in cost, overhead lines, more particularly distribution lines, are still more costly than they might be. In countries other than our own, the rural consumer has been specially catered for in a much less expensive fashion and without detriment to the public safety. It is pleasing to note, therefore, that suggestions have been made to the Electricity Commissioners that they should undertake a still further review of the Regulations within a reasonable period with the object of effecting still further reductions in the cost of overhead line construction.

Apart from the cost of actual construction, the cost of obtaining wayleaves and consents is in many cases much higher than it might be, owing to what may appear to be ill-conceived opposition on the part of certain persons and bodies. Such opposition is not infrequently met with and presented, irrespective of the merits or demerits of the particular case, and may savour somewhat of an attitude of obstruction. While rural electricity development is, owing to the enterprise of supply undertakings, making steady progress in certain parts of the country, the rate of progress is undoubtedly retarded by opposition of the nature referred to. This is a fact which the general public must be made to realize. Difficulties such as these will only be overcome in the course of time when the public generally become more enlightened as to the advantage to be derived from the development of rural industry and the improvement of rural conditions.

In this connection the Rural Community Councils which have been formed in certain parts of the country are doing good and valuable work. My experience is that these Councils are most willing to co-operate with the electricity supply undertaking, realizing, as they do, the advantage to be afforded by a rural electricity service and, at the same time, appreciating the fact that such service can only be given on reasonable terms if expenditure is kept within due bounds. Let us hope that these Rural Community Councils will continue to take a broad view on all matters in which they are interesting themselves, and more especially in regard to the necessary and proper use of overhead electrical distribution as being the only means whereby rural areas can be catered for.

No matter how anxious and willing a supply undertaking may be to carry out the electrical development of areas of the rural type, it must be clear to everyone that such work can only be put in hand if there is a reasonable prospect of the various schemes paying their way within a reasonable period of time. On the other hand, an undertaking which plays for safety all the time will make but little progress.

There are areas or parts of areas which admittedly cannot be catered for except at a loss. Such areas cannot be developed in the early stages. There are also areas where a sufficient income is readily obtainable without appreciable effort. Mid-way between these is the type of area which can be made to pay its way but only by the exercise of energy, forethought and determination, combined with the application of sound engineering and commercial principles. It is with such areas that several undertakers are doing their utmost to deal at the present time.

In doing so it has to be kept continually in mind that the margin between success and failure is somewhat narrow. If business does not accrue a loss is sustained. Enthusiasm alone is insufficient to combat such a position.

In order that business may come in reasonable volume and in such a way as to ensure commercial stability, it is essential not only that the selling price of the commodity should be right but that the charges made should truly and properly reflect the value of the service rendered. The fixing of the correct tariffs to be applied therefore becomes a matter requiring more than casual and haphazard determination. While this statement is really general in its application it is much more vital in its effect in the case of rural areas than in, say, densely populated industrial areas.

The cost of an electricity supply service—I use the term in its broad sense—is made up of two essentially distinct factors, viz. standing charges and operating charges. Allusion has already been made to the standing charges incurred by way of service of capital. There are, of course, other charges coming within the same category, one of these—and by no means an unimportant one—being that levied by way of local rating on plant and transmission lines. This in its incidence is not always as equitable as one might wish. While it is essential that all these charges should be kept within proper limits, it is equally essential that they should be met. They must therefore be reflected in some form in the electricity supply tariff.

The other factor, namely, the charges incurred in generating and distributing, referred to as operating charges, is perhaps more easily dealt with as bearing a closer relationship to the output when measured in units.

The vexed question of electricity supply tariffs has been the subject of a good deal of controversy for a very long time. It is a matter on which it is difficult to arrive at general agreement, although the underlying principles of a correct tariff are more or less generally accepted. Whatever views may be held, it must be conceded that the incidence and extent of the demand are material factors in the all-in cost of providing any particular supply of electricity. It is fully realized by all having knowledge of these matters that while, so far as its energy value is concerned, any one unit of electricity is equal to any other unit, the relative cost may differ very materially even when the supply is taken from the same plant and delivered in the same locality. This difference has to be taken care of in the tariff. An ideal tariff would be one which would automatically apportion in a proper manner the various costs incurred in furnishing the supply. This is somewhat difficult to attain and can only be arrived at by more or less close approximation.

Long-hour high-load-factor business should be encouraged, and, although purely short-hour lighting business has to be catered for, the price applying to such supply must be such as to carry a proper proportion of the standing charges. It is sometimes argued that a general improvement of the load factor on any particular system should result in a general downward adjustment of the price for all classes of supply. Such argument is fallacious and, if given effect to, would provide undue encouragement to the further development of low-load-factor business and result eventually in again lowering the average load factor on the whole system.

To provide and maintain what is the desideratum of all progressive electricity supply undertakings, namely, a high average load-factor on the system, the high-load-factor consumer must be given the full benefit of the advantages accruing from his particular conditions. These should not be passed on to the casual and intermittent user. The latter must be encouraged by other means to see the error of his ways.

A good deal has been said and written from time to time as to low tariffs for night load. Night load is all to the good so far as it improves, and is likely to continue to improve, the load factor on a system. One useful source of such a load is the electrical heating of water for storage and use during the day. The encouragement of such a service is worth while and no doubt apparatus will be forthcoming from the manufacturer in due course and at an economic price which will admit of its being fairly generally used. Meanwhile it has been suggested that such a supply could be given at practically the bare cost of fuel. The question is, however, "Can it continue to prove a stable condition?" There are a few undertakings having a daily load factor of the order of 50 to 65 per cent, even in winter months when the load due to lighting is at its maximum. It may be claimed that this is due to peculiarly fortunate circumstances. On the other hand it may be claimed equally that it is due to tariffs designed to encourage the more extensive use of electricity. Whatever the reason, it is clear that in such cases a night-load tariff based on the bare cost of coal might quite easily result in such an increase in the night load that additional plant would be necessary to cope with it. How are the additional charges to be met? Obviously by an upward revision of the night-load tariff. Any such revision would immediately call forth a justifiable complaint from consumers affected and would be accompanied by more or less permanent dissatisfaction. This is probably an extreme case and is simply put forward to emphasize the necessity of taking a long view in designing and fixing tariffs. It is essential that the ultimate effect on the cost of providing the service should be visualized and kept clearly in view when designing and fixing a tariff to meet any particular type of demand.

In the same way the question of the development of the general domestic load has to be considered in conjunction with its probable future effect on costs. It has been estimated that if the market for domestic coal in this country ceased to exist, the price of industrial coal would have to be advanced by at least 2s. per ton. This figure is given for what it may be worth and is only put forward to emphasize the advisability of taking the longer view and avoiding the possibility of creating future dissatisfaction amongst consumers who may otherwise feel that their business has been obtained under a misunderstanding.

There is no doubt whatever that, given proper, sound and fair tariffs, electricity can be sold for any purpose to which it can be applied, at prices which give satisfaction to the consumer and which, at the same time, provide a proper margin to the supply undertaker. In dealing with areas of the rural type, however, and in order to build up within a reasonable time the volume of business required to meet expenditure so involved, it is necessary to pursue a determined sales policy. One of the first essentials to a sales organization is a proper interpretation of the meaning of salesmanship.

Anyone can sell in large quantities almost any article at a giving-away price. That is not salesmanship. A brilliant salesman may for a time dispose of an article at very much enhanced prices. This does not make for permanence and cannot but result sooner or later in dissatisfaction and suspicion. The real salesman is one who has knowledge of the article for disposal, confidence in it, personal conviction as to the price being fair to buyer and seller alike, and the personality necessary to convey a similar conviction to those with whom he is dealing. It is the latter type of salesman that is required by the electricity supply industry. Even so, if he is to be a success in helping to develop the rural districts he must have still further qualifications. In the first place he has to set himself out to understand the point of view of the rural inhabitants. Those of us who have perhaps lived in towns and cities all our lives are apt to look upon the rural dweller as being somewhat simple and unsophisticated, and we may be apt to approach him accordingly. Experience teaches us, however, that we cannot get very far by doing so. We very soon learn that in general he is a very shrewd and careful individual. He is much more conservative than the town dweller. He is consequently more difficult to convince that anything which is different from that to which he has been accustomed may in fact offer him advantage by its adoption. This is perhaps another reason, and one which is sometimes not appreciated, why rural development does not proceed at a greater pace.

In order to hasten the pace of rural electrification it has been suggested in some quarters that a system of more or less intensive advertising should be developed. Advertisement by way of printed matter alone is of little use in rural areas. The organizing of lectures and talks, such as those provided by the Electrical Development Association, is, however, serving a useful purpose and is a matter in connection with which closer co-operation might be encouraged between that Association, the Rural Community Councils and the supply undertakings. No matter how hard all or any of these methods may be pressed, however, we cannot get away from the fact that personal contact and the desire to render the best possible service will provide the greatest and the most successful development. The best advertisement is, after all, the satisfied consumer.

No matter how earnest and sincere the supply undertaking may be in the desire to render public service, it is not sufficient to adopt a self-satisfied air and to stand quietly by pending the requisition of such services. The public in general are still woefully ignorant of the many uses to which electricity can be put and of the advantages, among which may be included the additional ease and comfort, which will accrue to them by such use. The education of the public is a matter which has to be taken in hand if progress is to be made. This may be accomplished in several ways, and perhaps the most general is by means of electricity showrooms.

The establishment of a number of showrooms by any one undertaker in each of several small towns or villages becomes a somewhat costly matter. There have to be met not only the cost of maintenance and attendance but also the cost of carrying substantially larger quantities of dead stocks. The question of showrooms is one in regard to which closer co-operation between supply undertakers and electrical contractors might with advantage be encouraged. In the case of rural areas the general provision of showrooms is ruled out by commercial considerations. It may be possible to acquire temporary premises for an occasional demonstration, but a more efficient and effective method is to provide a travelling showroom in the form of a suitably designed motor vehicle. Such a vehicle can be supplied with apparatus from one central showroom and can be sent out periodically with that type of apparatus especially suitable to the particular season of the year.

One of the difficulties which operate against the more rapid development of domestic load is the cost of appliances. This is a matter in connection with which the supply undertakers are entitled to look to the manufacturers to remedy. It is true that an attempt is being made to overcome this difficulty by the adoption of hire and hire-purchase methods. In so far as these methods result in increasing the demand for a specific article without encouraging the manufacturer to reduce the price where possible, they may be said to be wrong and to that extent they are bound to fail in achieving the desired end. It is pleasing to note, however, that certain manufacturers are themselves now willing to accept full financial responsibility for the hire-purchase of certain types of electrical appliances.

The electrification of rural areas not only provides advantages to the rural dweller, but should go a long way to assist in curing some of the ills resulting from modern industrial development. Such development has resulted in drawing industry and people from the countryside into crowded cities, giving rise to conditions which have produced the impression, in some minds at any rate, that what is good for business is not good for the people as a whole. While such an argument may be classed in the order of superficial philosophy it is still one which holds ground in certain quarters. By making possible the decentralization of industry without in any way impairing its efficiency—to put it no higher—electricity is providing a service the value of which it is impossible to calculate. If this may be claimed to be the true position it is extremely unfortunate that difficulties such as those to which I have referred as savouring of obstruction still continue to be placed in the way of more rapid electrical development.

These difficulties must, and will, be overcome, but courage, determination and enthusiasm are required. Let us see to it, however, that as engineers we do not let our enthusiasm outrun our discretion. Our industry must follow the natural line of economic progress, and if this is done the outcome cannot be in doubt. Not only efficiency in production but the efficient use of investment are the duties of any undertaking, whether public or private, and if any other course is taken the reckoning is bound to come sooner or later. Let us ever keep these facts in view so that our job may be carried out in such a way as to realize the only true and proper aim, namely, the provision of mutual benefit to the public whom we serve and to our own industry as one worthy of the public's hire.

DUNDEE SUB-CENTRE: CHAIRMAN'S ADDRESS

By R. J. LAWSON, Member.

"USE AND ABUSE OF MAN-POWER."

(ABSTRACT *of Address delivered at* DUNDEE, 10*th October*, 1929.)

We, as electrical engineers, belong to a profession of great importance to the well-being of our fellow-men, a profession which calls for a very high standard of efficiency from its members, irrespective of grade. We are responsible for the development of the application of electrical science, which has a considerable bearing on the degree of prosperity of our nation. For, as Herbert Spencer says, the manufacturer "who uses a bad machine cannot compete with another whose machine wastes less in friction and inertia. . . . The ability of a nation to hold its own against other nations depends on the skilled activity of its units. . . ." Because of this need of efficiency our Institution is indispensable to members of our profession. It provides an avenue through which the development of electrical science is made known to all interested. The quality of the papers published in the *Journal* is of the highest order and our monthly meetings help to keep us from getting into grooves—as Matthew Arnold says, "each day's petty dust obscures our vision."

I should like to suggest, therefore, that we look upon these meetings as a training ground for self-expression in public. As engineers we deal with public bodies, all classes of men—business and professional—and it is a valuable asset to the technical officer to be able to express his ideas in a clear, reasoned and cultured manner. I would urge that it is to the personal advantage of all members of the electrical profession to take a keen working interest in the affairs of the Institution.

I shall now proceed to discuss the subject of my address, viz. "The use and abuse of man-power"—a subject which I feel is boundless.

The present age will probably be known in the future as the "speed age." In the air, on the earth and on the sea, in trade and commerce the daily cry is "Increase your speed," "Increase your output per unit." To-day the manufacturer is burdened with heavy taxes. He has difficulty in competing with foreign countries because his prices for goods are higher than those of his competitors.

We realize that we must earn our daily bread. Nevertheless, there is a suspicion that those in authority forget that, to be of real value, all advances in the wealth of a country must tend towards a higher civilization and a higher type of manhood. They seem to forget, too, that the building-up of our manhood should come before the building-up of a petty bank balance. It is a commonplace to say that the wealth of a nation depends on its manhood. Perhaps I may, without being misunderstood, state that the wealth of a nation *is* its manhood.

Nevertheless we are faced with high costs in production. To reduce these many suggestions have been made, amongst which are the following:—(*a*) Reduce the wages of the manual worker; (*b*) Keep a young staff; and (*c*) Reduce all costs by from 10 per cent and upwards. I would describe (*a*), (*b*) and (*c*) in the words of Prof. Clay in his address on "The public regulation of wages in Great Britain," as "instances of the operation of the habit described by Dr. Cannan as 'proposing remedies for economic pressure without considering the question whether that pressure may not be an integral part of the existing organization which cannot be removed without causing disaster unless some efficient substitute is provided.'"

Early in the present year one of our prominent business men, in a lecture dealing with the outlook of commerce, advocated the use of up-to-date machinery, education on commercial lines, and careful organization.

One of our English newspapers stated that the recent trade trouble in Lancashire was due to "the rapid development of machine manufacture in the East and the Far East," and gave it as its opinion that British mills should be equipped with the best and latest machinery and directed by alert and progressive minds.

Quoting again from Prof. Clay's address, he says: "Lord Passfield and Mrs. Sidney Webb in their classic study of the effects of collective bargaining had laid chief stress upon its influence in increasing the efficiency of labour." The point that I wish to lead up to is that if we as a manufacturing nation are to keep our place in the world's markets we must have trained, efficient workmen interested in their work.

From observation, from inquiry and from experience I suggest that the interests of many of our workers have been diverted from legitimate to other channels. Workmen are not interested in their work, the reason probably being that they have not been taught the best way to handle tools. They do not appreciate the beauty of craftmanship and the dignity of workmanship, and their work is drudgery to them.

Newton said: "I have been able to accomplish what I did because I stood on the shoulders of giants." Again: "Men of the largest original power make the most use of the results obtained by other men." In music, art, literature, law, politics, sport, etc., we do follow Newton.

Bacon says: "Habit, if wisely and skilfully formed, becomes truly a second nature . . . but unskilfully and unmethodically directed it will be, as it were, the ape of Nature, which imitates nothing to the life, but only clumsily and awkwardly."

Two workmen, "A," fairly old, and "B," a younger man, were employed in the same workshop, on the same class of work and at the same piece-work rate. "A" had been trained under a master-craftsman, but "B" had not been so fortunate. "B" was a spectacular worker and visitors to the works invariably stood and admired the speed at which he worked, while they ignored "A," but "A" always earned the larger weekly wage. He required fewer strokes "to drive the nails home." Each knock counted, and consequently his output of work was greater. "B" went through many unnecessary movements which were wasteful in time and physical energy.

The point I wish to make is that if a man is to give his maximum output of accurate work as a normal and natural day's output he must in his youth have training in the art and practice of workmanship under a first-class workman, as a natural high speed of workmanship with accuracy is fundamental to low cost of construction. Let me put the matter in another way. Each man in his apprenticeship and early manhood develops what might be called his natural speed of movement. If, however, pressure be applied to obtain an increased working speed I suggest that the law of a "permanent set" would apply and something would give way. Further, I suggest that a man's working speed is determined by his early training and early environment.

I am certain that the need for the careful training of the youth in the art of workmanship is fully appreciated by our universities and our technical colleges and schools, and much is being done by these bodies towards this training. There is evidence, however, that in spite of the work of our colleges the practical training of the man whose life work is manual is not meeting to-day's requirements. It must not be forgotten that to-day we are in competition with foreign workmen who are in earnest. In the interests of self-preservation every man ought, therefore, to be fully trained in his particular calling to enable him to contribute his full complement of effective work of a high standard. To me the question naturally arises "Are we making full use of our man-power, which is of a very high order when cared for?" In other words, are our manual-work apprentices being fairly treated by their employers? Inquiries which I have made in many quarters have elicited the information that apprentices are being used as errand-boys, sweepers, etc., and that they are rarely taught the art of workmanship by a master-craftsman during working hours. This defect is, as I have said, being met to a degree by the evening technical classes.

The serious responsibility towards youth is thus emphasized by Herbert Spencer: "Is it then that the unfolding of a human being in body and mind is so comparatively simple a process that anyone may superintend and regulate it with no preparation whatever?" The conditions of business life to-day call for a very serious review of the steps taken to train or to develop the youth in the art of workmanship. The methods of certain firms in the training of apprentices tend to destroy the interest, the zeal for work and the enthusiasm of the average youth.

Before dealing with a constructive policy of training let us consider the broad question of education. Referring to this subject Herbert Spencer reminds us that amongst primitive people adornment comes before dress, and says: "It is curious that the like relations hold with the mind. . . . Knowledge which conduces to personal well-being has been postponed to that which brings applause. So a boy's drilling in Latin and Greek is insisted on not because of their intrinsic value but that he may not be disgraced by being found ignorant of them. . . . Definitions, rules and principles being put first instead of being disclosed as they are in the order of nature through the study of cases. . . . What with the perceptions naturally dulled by early thwarting and a coerced attention to books; what with making the pupil a mere passive recipient of others' ideas and not in the least leading him to be an active inquirer or self-instructor, and what with taxing the faculties to excess—there are very few minds that become as efficient as they might be. Examinations being once passed, books are laid aside; the greater part of what has been acquired, being unorganized, soon drops out of recollection—what remains is mostly inert. The art of applying knowledge not having been cultivated, there is but little power either of accurate observation or independent thinking. . . . While the rule-taught youth is at sea when beyond his rules, the youth instructed in principles solves a new case as readily as an old one. . . . In education we are finding that success is to be achieved only by making our measures subservient to the spontaneous unfolding which all minds go through in their progress to maturity."

"With few exceptions men are employed on the production, preparation and distribution of commodities. The efficiency of the employee depends on an adequate acquaintance with their physical, chemical and vital properties—otherwise science—which, according to Matthew Arnold, is confined to the domain of knowledge. . . . This order of knowledge . . . is the order of knowledge underlying the right performances of those processes by which civilized life is made possible."

We press for knowledge without considering that the question is not whether such or such knowledge is worth while but what is its relative value to a working electrician. One must be prepared to be ignorant of many things to be master of one's calling.

So far as the education of the young is concerned, I have said sufficient to indicate that our ideas and methods of education require careful review, and a number of societies are aware of the weakness of education and are working towards an improvement. To quote William Jones: "The great end of all education is to make our nervous system our ally instead of our enemy. For this we must make automatic and habitual as early as possible as many useful actions as we can, and as carefully guard against the growing into ways that are likely to be disadvantageous."

Lord Riddell tells of a man who can be relied upon to state accurately what a letter, memorandum or Act of Parliament contains, but who invariably gives an inaccurate account of a conversation. He is perceptive through the eye, not through the ear. I therefore suggest that a few men learn through books, but the majority are educated through their hands, and it is with the education of those who handle tools that I am concerned. I am concerned because it is largely on the manual worker that our well-being depends.

Let us pursue this a stage further. If the handiwork of a manual worker is equal to the design of the brain-worker we have a complete article exactly as the design. In other words, to produce there must be the labour of the designer and the manual worker. The knowledge of the latter must be such that he can interpret the work of another's brain. Now if the knowledge of the brain as indicated by a written paper can be assessed by the certificate issued, why should the same knowledge as indicated by hand-work not be assessed and a certificate issued accordingly? Let us examine this as to its bearing on the attitude of men to their work. The award of a certificate tends towards self-respect, and to work for it develops manly characteristics. Therefore, since to-day's needs demand thorough training, I suggest that before an apprentice joins a firm he should be required to attend a school of instruction in practical scientific work for a period of six months or more. The school should be attached to works of standing or to technical colleges situated in convenient centres. The teachers selected should be outstanding manual workers noted for their method, zeal, accuracy and punctuality, and inspired with the real spirit of craftsmanship and a thorough working knowledge of their jobs. The main point which the teachers should strive for is the development of the youth into a naturally quick, accurate and intelligent worker. A few of the fundamentals are:—The handling of tools in a naturally easy manner, i.e. the elimination of all unnecessary movements; training in the care of tools and material; method and order in the laying and the carrying out of works; thinking in advance to avoid an interval between stages of the same work; the habit of starting work punctually; the habit of thinking of time in terms of money or cost. The youth should realize that loss of time represents increased cost. The loss of 10 minutes per day represents a loss to the firm of one week's wages per man per annum, which adds to the manufacturing price of the article and tends to keep down wages. The youth requires to be told of this so that he may learn early to be diligent. The honour, the dignity and the importance of manual labour well done should be emphasized. The youth should be taught that the well-being of humanity depends on the efficiency of labour, that the manual worker who goes about his duties as an interested, intelligent man with a full working knowledge of his calling is indispensable.

As I have already stated, a workman, to be efficient, must have an adequate acquaintance with the physical properties of the material on which he is engaged. Further, the working electrician, to be master of his craft, must possess a working knowledge of the laws of electricity. As the period of apprenticeship is necessarily short, we can only consider knowledge of relative worth to a working electrician. Then there is the difficulty of imparting such knowledge. For the youth, when starting his class work, has not sufficient experience of the practical side of his trade to enable him to assimilate the theoretical part of the subject, and consequently interest in class work is often destroyed. Therefore, to maintain and to increase the youth's interest in his trade education I would combine practice with theory.

If the various points of interest in his work were explained to a youth by a capable, patient teacher while the youth was handling the material, the knowledge so gained by the apprentice would remain with him and be a real help. This would be education of everyday value.

How valuable it would be to the electrical industry if before an apprentice joined his firm he had acquired the correct method of handling tools and material. He would know how a job should be laid out, and he would understand the working laws of electrical science. What he now requires is experience or a chance to put into practice what he has learnt from masters of his trade, and that without hindrance.

At the close of the period of training the youth would be examined by an independent examiner in workmanship, with special reference to method. No written examination would be required. At the end of each year the employer would report to the training centre as to the boy's progress and experience, and the apprentice would present himself at the training school for an annual test in workmanship. After a recognized period of practical experience he would be eligible to undergo his final test. A youth attaining a certain standard of efficiency as a workman would be awarded a diploma certifying that the owner was a fully qualified working electrician.

The serving of an apprenticeship is not a guarantee that a man is an efficient tradesman. The importance and complexity of electrical works demand efficiency, which can only be attained by careful selection and a thorough training. Lord Passfield and Mrs. Sidney Webb lay stress upon the influence of collective bargaining in increasing the efficiency of labour. That may be so, but to me it seems that efficiency can only come through training, experience, interest and knowledge, and should precede bargaining. There is neither progress nor development amongst men whose pace is kept to that of the inferior and the slowest worker. Another fallacy, expounded by certain types of business man, is that college men are not so useful in business as the youth who goes to business direct from school.

The conclusion at which I have arrived is that fully trained workmen who are interested in their business are essential to-day, and that we are not delivering the goods. To offer a remedy is not easy, for one of the factors is tradition, and another is that it is no one's business to tackle an unpalatable trade question which is calling for review. The question, however, is, so far as Scotland is concerned, so important that it must be tackled, and the sooner the better.

Let us see, from our standpoint, what might be done.

A man's standard of knowledge to-day is measured by his ability to pass a written test of his knowledge of a subject or subjects. To the successful student a certificate is issued which indicates the student's degree of knowledge. There are difficulties in the way of introducing any scheme which interferes with tradition. What has been good for the father should be good enough for the son. Of course it has not been sufficiently good for the father, and conditions have changed. Further, if there were no difficulties to be overcome the engineering profession would die. I suggest, therefore, that if members in positions of influence in London and other large Centres combined with influential employers of high standing and the City and Guilds Engineering College, a practical scheme of training could be evolved, the fruits of which would be felt through the industry within the next few years. The improvement in the standard of men and work and the increased output per man would more than repay the expense of the training classes. Further, I suggest that as such training would lead to a recognized diploma it would create an interest in his job, and give pleasure to the worker.

There is still another factor to be discussed, namely those in authority. One writer says: "Insincerity, shiftiness and bluster have too often won the ear of the foolish and clouded the discerning eye." Again, "The perpetuity of organized life depends on the rise of superior men into positions of authority." The point which I wish to make is the fundamental need in the interests of output for the pull to be in one direction, namely towards good business and plenty of it. The responsibility for this rests mostly on those in authority. The working efficiency of an engine is regulated by the interest taken in the engine by the driver, who sees that all the bearings are free of friction. In a word, the engine is well cared for. So with man; he rises to his maximum efficiency under correct treatment. As John Graham says: "Every man is a special case and needs a special pill," and "You cannot work individuals by general rules."

G. K. Chesterton says: "There is a great man who makes every man feel small. But the real great man is the man who makes every man feel great." It is agreed that hard words are sometimes necessary, but before using them one should be sure of all the facts of the case. A word of well-deserved appreciation should never be omitted; it is a wonderful lubricant and a fine thing for increasing interest and loyalty towards the firm.

It is said that a competent chief can move among his men without having to draw an imaginary line between them, because they will see the real one if it exists. I refer to this because there are gems to be picked up which are often missed by false notions of one's dignity. Let me illustrate my point. Some years ago a promising young man was attached to a local firm. He was a capable and loyal employee; he was pulling his full weight in the interests of the firm which, as a direct result, was forging ahead. Those in authority continually grumbled at this energetic servant until the latter had to resign. To-day that man is at the head of one of the most widespread engineering firms in Britain. To carry this thought further I should like to remark that human nature is, in the interests of self-preservation, most adaptable. A young man of spirit and ambition who knows his business will not allow the development of his manhood to be interfered with by another man. He will seize his opportunity to strike out for himself. Initiative is a sensitive attribute and is easily destroyed; when wisely developed it is invaluable in all grades of men. Yet it often happens that those in authority, instead of wisely developing and guiding this important characteristic in youth, tend to curb it. Consequently there is the danger of such men never developing to their full degree of efficiency; they are as pawns in the game before they reach middle life. What happens to the many eager apprentices? Perhaps their wings have been clipped and in self-preservation they have adapted themselves to the whims of control until they have no power to think and to act wisely in a crisis—they must await instructions. An efficient head of a business should understand human nature; weld the team into one whole; develop the intelligence of the men so that the spirit of the instruction as well as its letter is understood and followed; and engender amongst the staff the spirit of interest, co-operation and loyalty.

John Graham tells of a young man who, on the death of his father, found his possessions to be a strong, clean, healthy body and a well-trained, educated mind. The only job available for him was one of manual labour, which he undertook. He applied his educated mind to his work and in time detected weaknesses in the organization. He accordingly suggested other methods which proved a saving in man-power and costs. The firm had, in its own interests, to adopt the newer ways, and incidentally the young man was promoted. This continued until he was appointed to the board of control.

Everything else being equal, the man with the best knowledge of industry and a fully developed brain is the man for the highest posts. I come back to the question of early training and its application. The man who can apply to business his university education has the advantage throughout life. On the other hand, the lack of the application of education in industry impoverishes industry. To be of value the fruits of education should enrich business, industry and leisure. Training and hard work tend towards success in industry. Work is a noble game with a trained team who respect the laws of the game. The playing ground has many hazards to maintain the interest of the players, and the results of the game depend on the degree of co-operation given by the players of all grades.

SHEFFIELD SUB-CENTRE: CHAIRMAN'S ADDRESS

By H. W. WALKER, Associate Member.

"LEAVES FROM AN ENGINEER'S NOTEBOOK."

(*Address delivered at* SHEFFIELD, 16*th October*, 1929.)

I selected this subject in the belief that a chairman's address should deal with matters of general interest to members rather than with some specialized subject of a highly technical character.

Nearly 20 years ago, whilst serving as junior engineer on the staff of a large power supply company, I wrote an article in which, after drawing attention to the many supply systems and power companies then in being, I remarked, with the optimism of youth, that ultimately it would only be necessary to link up the various concerns and Dr. Ferranti's "all-electric scheme" would become almost an accomplished fact. The linking-up process has now been commenced in earnest, and in many districts the lines have already been erected under the national scheme. Standardization of supply voltage and frequency will follow. A tremendous saving in conversion costs could have been effected had the matter been dealt with some 20 years ago. It has been suggested that the War period delayed the adoption of interlinking, but in my opinion this period advanced, rather than retarded, this development.

Many of us have wondered why railway electrification has not been developed in conjunction with the "grid." Possibly financial reasons were the chief obstacle, but the "grid" has undoubtedly been designed to facilitate railway electrification; and, with a commission of inquiry appointed to examine the matter, it would appear that the omission may shortly be rectified.

The next 20 years should show much more rapid progress in the demand for electricity for specific purposes. Any improvement in trade will soon be reflected in an increased demand for electric power in our great industrial centres, and in the event of a boom the national interconnecting lines, acting as equalizers, will enable the supply and demand to be dealt with more efficiently.

Rural industries and agriculture will be greatly facilitated by the extension of supply areas. Very large increases in domestic load will be experienced when the price per unit encourages cooking and heating by electricity in every household, as at the present time not more than 20 per cent of the houses are wired. Heat storage during the night is also a promising development and provides a means of considerably improving the load-factor curves.

With electricity "on tap" in the rural districts a great demand for lighting and power should be experienced, provided publicity is given to the matter. If villages in the Alps, at an altitude of 3 000 ft., can have their streets and houses electrically lighted, surely villages in this country which are richer and more prosperous should enjoy similar luxuries.

During a conference of lighting experts held in this city last year examples of street lighting by means of improved electric fittings were demonstrated and proved a great advance on the old style of gas lamp, so familiar to our grandparents and still in common use to-day. In spite of this the boulevard approach to one of our new universities has a splendid array of modern lamp pillars each fitted with a gas lamp, with the hanging-chain method of individual lighting and extinguishing. May we regard this as indicating a step forward, or backward? Few of our large cities so far appear to adopt electricity exclusively for street lighting, but almost all of them do so for illuminating their main streets and busiest thoroughfares. Electricity cannot always compete economically in places where gas companies have long been established and have all their mains laid, but in new streets, country towns and villages where a supply is available it undoubtedly can do so.

CHANGES IN PLANT.

It is to be regretted that the electric steel-furnace has dropped so much into disuse, many of the furnaces standing idle and some being dismantled altogether. Is this entirely due to the state of trade?

We are all aware that an electric-furnace load is not a really attractive one to the supply authorities, but these furnaces found favour and were a great national asset during the War. It seems a pity that those already in existence cannot be made use of, especially in view of the fact that foreign steel used in Sheffield could easily be made here, although foreign basic material might be necessary for producing the high quality of steel in demand. If the cost of current is prohibitive, why not encourage a night load by a substantial reduction in price during certain hours?

The high-frequency furnace appears so far to give great satisfaction to those concerned in its operation. With a reduction in cost, its use should be greatly extended, but an improvement in the design of the condenser units is needed in order to achieve complete success. A particularly irritating fault experienced with this type of furnace is that the container, being made of refractory material, is liable to fracture during a heat, thus releasing the molten metal. In such cases not only is the wooden casing burnt, but the tubular copper-coil element may be irreparably damaged. An improvement in the construction of the refractory containers, etc., is urgently needed.

I recently noted, with some surprise, a newly-installed rolling-mill driven by a crude-oil engine situated in the centre of an electric supply area. In my opinion such a plant cannot possibly compete as regards overall life, efficiency and reliability with an electrically driven mill, and I mention the matter to indicate that electrical engineers must still be alert to such competition.

So far as the electrical manufacturing industry is concerned, one may remark that it defies competition. The percentage of foreign electrical plant purchased in this country to-day is negligible, the chief reason being that our electrical manufacturers have risen to the occasion and cheapened their productions to a greater extent than any other engineering product on the market.

This applies perhaps especially to small and medium-sized motors and their accessories, which are procurable at extremely moderate prices and really represent remarkable value. The opinion is sometimes expressed that prices to-day are rather too keen and the rating too exacting. For the large saving in material effected by improved design and ventilation, and the smooth and silent operation which is so noticeable, our designers deserve great credit.

FAILURES OF PLANT.

No other power plant will run in such hole-and-corner positions, or under such neglected conditions, as electric motors frequently have to do, and yet complaints are made when breakdowns do occur.

Records of electrical plant in use in every class of industry, and under very varied conditions, show an average breakdown figure of approximately 7 per cent per annum. The term "breakdown" is applied to failures that necessitate dismantling and repair of the plant, as distinct from the renewal of bearings and similar work which is more correctly regarded as maintenance.

The following analysis of the causes of breakdown may be of interest, although it applies only to generators, motors and starting-gear. The figures are based on experience during the year 1928, and cover several thousands of machines of various ages.*

Analysis of Causes of Breakdown of Plant.

Cause	Generators	Motors	Starting gear
	per cent	per cent	per cent
(1) Accidental	15	20	19·8
(2) Dust, oil and neglect..	37	39	33·4
(3) Age and deterioration	20	22	18·4
(4) Faulty work and design	5	4·6	6·4
(5) Overloading	11	7·2	11·6
(6) Unascertained ..	12	7·2	10·4

It will be appreciated that these figures can only be approximations, because in many cases the effect of the breakdown is to destroy evidence of the cause. However, to deal with the figures generously we may conclude that lines (1) and (6) comprise quite unavoidable *bona fide* breakdowns, and in round figures constitute about 28 per cent of the *total*. The three causes specified in lines (2), (4) and (5) are normally avoidable and account for about 52 per cent of the breakdowns. Whilst "age and deterioration" is responsible for 20 per cent, it must be remembered that this figure is increased by "oil, dust and neglect" and "overloading."

It should be noted that the above figures relate to plant which is subject to a regular inspection service, each item of plant being regularly examined and carefully watched to detect any irregularity in operation. If this is the experience with plant subject to an inspection service, it may be assumed that the figure of 52 per cent will be very seriously increased in cases where no such regular service exists.

If the detailed costs of these breakdowns, including not only actual repair expenses but also the cost of works stoppage and inconvenience, were fully appreciated, many large users of electrical plant would adopt a system of regular inspection. A complete register of all items of the plant should be kept, and records of tests, rotor clearances, etc., and the general condition of each item, should be entered after each examination. Such a system would result in the prevention of many costly stoppages, and in the event of failure the records prior to its occurrence would be available to assist in avoiding a repetition.

In some instances where this procedure has been adopted the old adage that "familiarity breeds contempt" is often demonstrated by the negligence of the maintenance staff. It is mainly for this reason that many important firms employ specially trained outside engineers to make periodical inspection of their power plant. Such inspections are defined by Government departments in the case of boilers, pressure vessels, lifts and cranes, and also in the case of coal mines. If this procedure were enforced in connection with electrical plant generally, the advantages would be very great indeed and would lead to more efficient and safer working. Official interference, as this may be termed, is, of course, very objectionable to many of us; but it is probable that some such regulations will be issued in the near future.

It is not my intention to create an impression that electric motors are peculiarly liable to breakdown, but rather to suggest the causes of some avoidable failures, and if possible to reduce the percentage of breakdowns.

DIRECT-CURRENT MACHINES.

Direct-current motors are fast disappearing from public supply systems and are being replaced by a.c. machines; many private firms also are discontinuing their use, but large numbers are still in service.

The most vulnerable part of a d.c. machine is the armature, and, in a large proportion of the breakdowns, failure of the windings is attributable to commutator defects. Oil and dust deposits at the ends or on the surface of a commutator are the most frequent causes of short-circuted bars through carbonization of the mica, earthing of the V-rings, etc., but the leakage paths at the ends of a commutator are often quite inadequate. In other cases the mica inter-segments are much too thin for continued satisfactory operation.

Paste-filled commutators have proved quite unsatisfactory and should never be constructed. As regards those already in existence, the only remedy when trouble is experienced is to reconstruct them completely and to fit sections of good Canadian amber mica.

---

* My acknowledgments are due to Mr. E. G. Hiller, chief engineer to the National Boiler and General Insurance Co., Ltd., for permission to publish these figures.

Clamping and locking rings and bolts should all be of steel, and the means of securing these, whether by bolts or threaded ring, should be at the front end, the whole commutator being mounted on a separate sleeve securely keyed to the shaft. Incidentally, the bursting of a large commutator some 3 ft. 6 in. in diameter was due to the use of cast-iron V-rings, the metal having crystallized.

With modern former-wound coils, impregnated and well insulated, very few pure winding faults are experienced, provided adequate space has been allowed in the slots and end windings. Yet, even where the greatest care has been exercised in forming and insulating the coils, one frequently finds that the insulation of the coil-supporting rings is quite inadequate. Quite recently the armatures of three 200-kW rotary convertors, less than 2 years old, had to be reconstructed for this simple reason.

Impregnation of armatures under vacuum is recognized as good practice when good-quality varnish is used, but when poor-quality varnish mixed with a proportion of shellac is substituted windings have literally to be dug out, rendering the replacement of separate coils an impossibility.

Steel-wire binders wound on mica insulation, the core being slotted to receive them, form the best means of securing the coils in the slots. If the binders are run on the core face they are apt to slip or become displaced in handling. Should phosphor-bronze wire be necessary, great care should be taken to see that the wire is ductile and is not made brittle when being drawn. Two recent serious failures of d.c. turbo-generators have been traced to the bursting of phosphor-bronze wire binders. Of course, phosphor-bronze wire is only used in cases where the induced currents in steel-wire binders would cause serious overheating, an example being the case of a multi-layer binder of a high-speed generator.

Fibre or wooden wedges often cause trouble owing to shrinkage, and this method is therefore open to criticism.

Armature cores should always be built on spiders, except in very small machines. When the cores are mounted direct on the shafts it is difficult to key them effectively, and they tend to become loose in operation, especially in the case of gear-driven plant.

Regarding shafts, reductions need filleting as much as possible, and every manufacturer should appreciate that the journal should be larger in diameter than the extended portion carrying the pulley, whether bushes or ball bearings are to be fitted.

When field coils are wound with cotton-covered wire on spools and the end turns are reinforced, very little trouble is experienced, especially if the whole coil has been impregnated; but if enamelled wire is used, and the coils are liable to dampness or overheating, defects quickly follow owing to the enamel cracking and scaling off.

Frequently the burning out of a field system or the puncture of a field coil is traceable to a startor. Very definite and reliable contacts are required on a d.c. motor startor in order to complete the field circuit and to ensure absence of variation or rupture of the field current. Costly repairs in rewinding field coils have been caused by an intermittent contact on a startor, aggravated by local vibration.

A different type of brush gear is used on almost every different make of machine, and it is satisfactory to note that attempts are being made to standardize brush gear. A substantial box-type holder having an adjustable spring, with a heavy pigtail connection between the carbon and holder, is to be preferred. It is insufficiently appreciated that the selection of the correct grade of carbon brush is essential for satisfactory commutation.

For instance, an uncommon failure of a large generator, costing £200 to repair, was recently traced to the use of an unsuitable grade of brush. Sparking had been experienced, and in order to remedy this a harder grade of carbon brush was fitted and in addition the mica sections were slotted. Sparking ceased, but after a few days it was found impossible to maintain the correct voltage, although the shunt resistance was cut out and the engine speed increased. Investigation showed that the field coils and armature were burnt out, due solely to the hard brushes causing copper drag in patches around the commutator and short-circuiting the bars.

Alternating-Current Machines.

As our future interests are mainly concerned with a.c. machines, a few points regarding them must be considered.

The necessity for fine clearance between rotor and stator is the chief cause of failures in a.c. motors, and probably 50 per cent of these failures are due to fouling between the rotor and stator. This class of breakdown usually necessitates very expensive repairs, and some simple protective device which would effectively prevent fouling would be of inestimable value to users of a.c. motors.

Light auxiliary windings, or splitting of the stator phase windings, can be so arranged as to balance when the clearance is equal all round the air-gap and to trip the circuit breaker when a certain difference in clearance has been reached. Such protection, however, must be applied during construction and adds considerably to the cost of the machine.

It was anticipated that the introduction of ball and roller bearings would eliminate this class of failure, but, since the clearances have also been very much reduced, the desired results have not been obtained in practice. Contrary to the expectations of some users of electrical plant, ball and roller bearings do wear out. Creeping of the inner races and wear of the shafts or bearing housings are often the result of unsuitable drives and account for much of the trouble experienced with this type of bearing. For large machines the white-metal lined sleeve bearing is usually preferred.

Fouling between rotor and stator cores is a most serious matter in large motors and can only be avoided by keeping a careful watch on the working clearance. Mere checking of the clearance by means of a feeler gauge with the machine stationary is often misleading. An additional check is to open-circuit the rotor by lifting the brushes and then close and open the stator switch. The clearances in these circumstances will approximate more closely to those which obtain under working conditions than will those observed with the stator unenergized. The magnetic pull on the rotor is, of course, only in proportion to the current circulating in the stator circuit, so that, if only a slight movement of the rotor is observed, immediate attention to the clearance is often necessary. By applying this test it is possible not only to discover whether the bearings are worn or loose in the housings, but any looseness of the rotor or stator core can often be detected.

With well-designed former-insulated coils, the stator and rotor windings of large low-speed machines have proved very reliable. They are characterized by ample spacing between coils and leads, and it is quite practicable to replace separate coils without disturbing the whole winding. There are, of course, exceptions.

These good features are not frequently found in medium-sized machines, and seldom in small ones. Many makers use " mush " windings as the standard for small machines and, judged solely from a manufacturing point of view, these are cheap, uniform and quite satisfactory. Unfortunately, owing to the compactness of the windings, complete rewinding of the stator or rotor is usually necessary in the event of any winding defect, however slight. In very few cases is it possible to thread in a new coil with the correct number of turns, and in order that this may be done the windings must be well spaced and clean.

With concentric grouped coils and a 2-layer winding, in the event of short-circuiting or earthing of a coil, even should this be in the back layer, replacement of about 3 pole-groups may be quickly and cheaply effected. Should breakdown occur, the chain-type winding referred to is therefore a desirable feature from the point of view of the plant owner and repairer.

There is still much controversy as to the best method of construction of the squirrel-cage rotor. End connections are found soldered, brazed, welded, and cast on, and rotors constructed with any one of these methods are to be found working satisfactorily. On the other hand, all the methods used cause far too much trouble for present-day practice to be regarded as final, and the ideal means of securing rotor end-connections has yet to be found.

The construction employing soldered end-rings has largely fallen into disuse, but has the merit of limiting damage, frequently to mere disconnection of the soldered rotor end-rings, in the event of an open phase in the stator circuit or fouling between rotor and stator. With the other three methods of construction, burning out of the stator winding often results under these conditions, and the cost of repair is very greatly increased.

At a recent discussion* on squirrel-cage induction motors, tables were published comparing breakdowns of slip-ring motors with those of squirrel-cage machines. The following figures were given:

Slip-ring motors.
Stator breakdowns: 27·8 per cent.
Rotor breakdowns; 35·4 per cent.

Squirrel-cage motors.
Stator breakdowns: 68·3 per cent.
Rotor breakdowns: 14·7 per cent.

With the squirrel-cage type of motor, rotor failures are 20·7 per cent less, but stator failures are 40·5 per cent higher, than with the slip-ring type. It is quite possible that the indestructible-type rotor accounts for the higher percentage of stator breakdowns in the case of squirrel-cage motors, suggesting that the rotor with soldered end-connections has some advantages over other types, at any rate until an indestructible stator is produced.

The following exceptional failure is an example of what may be expected if rate-cutting and reduction in clearances are continued. A 110-h.p. 720-r.p.m. motor was started up on a cold morning and, as occasionally happens, the oil rings refused to function. The machine stopped, and when the attendant attempted to start up again serious internal arcing occurred, causing fusion of the windings. On attempting to dismantle the motor for repairs, it was found that the rotor was jammed in the stator tunnel, and all efforts to remove it failed completely although a 40-ton hydraulic jack was pressed into service. The only alternative to scrapping the machine was to force the stator core out of the frame, remove the stator windings, and dismantle the stator core a few plates at a time. This was eventually done, and it was found that fouling had occurred between rotor and stator to such a degree that the teeth of the rotor and stator had become welded together around the whole rotor circumference, for a width of about 2 inches between the first and second rows of ventilating ducts. The original clearance of this motor was barely 15 mils and, as it was constructed with pedestal-type bearings, alinement to give equal rotor clearance all round was a very delicate operation. Fortunately this is an unusual case, but it serves to illustrate the disastrous effects which extreme competition may have upon design.

Standard industrial motors of the semi-enclosed type, with large fans at one or both ends, are in some cases unsatisfactory. The amount of enclosure is insufficient to keep out harmful dust, but tends to retain it, and also makes the machine awkward to clean and examine.

Totally enclosed or pipe-ventilated motors, designed to comply with the appropriate British Standard Specification, are the only machines which can be regarded as suitable for working in dusty situations or under conditions where attention will be infrequently given. Such machines should preferably be provided with bearings of the roller type and with covered holes to permit checking of the air-gaps. Removable covers should also be fitted over the slip-rings.

ACCESSORIES.

Many of these are quite unsuitable for use in connection with power plant.

Frequently one comes across an extremely robust iron case only to find, on opening the cover, badly-spaced fittings, flimsy contacts and impracticable terminals. The current-carrying capacity of a great deal of such apparatus, especially fuse fittings, is very much overrated. Overheating of contacts and arcing on to the iron cases causes many serious defects and stoppages.

OIL-IMMERSED APPARATUS.

With oil-immersed gear the condition of the oil is of primary importance. It should be tested at reasonable intervals, and if moisture is found to be present, or if sludging has taken place, it should be cleaned by passing through a centrifuge.

---

* *Journal I.E.E.*, 1928, vol. 66, p. 438.

Moisture in the oil, due to varying temperature and atmospheric conditions, is probably responsible for more transformer breakdowns than any other cause. This is not altogether surprising when it is realized that a moisture content of 0·01 per cent may reduce the electric strength to one-tenth that of dry oil. If sludge is allowed to remain in the tank it tends to clog the circulating ducts, lowers the flash-point of the oil, reduces heat radiation, and in time becomes caked as hard as charcoal on the bottom of the tank and coil surfaces.

In the event of excessive vibratory humming the transformer should be lifted and the clamping devices tightened and locked, otherwise the movement will cause rubbing and chafing of the coils, leading to subsequent failure. Many transformer failures are due to such abuses as overloading or neglected inspection, but troubles due to pressure surges sometimes occur.

Years ago transformers were installed in any out-of-the-way place, and, whilst it may be admitted that many of these, mostly of the air-cooled type, gave little or no trouble, it should be remembered that this was before the days of e.h.t. transmission and before very large capacities were required. Recently I came across a case of an oil-immersed transformer, long neglected, which had completely burned out. The oil had become so heavily sludged that deposits had to be shovelled out of the tank.

In recent years oil-immersed static condensers have come to the fore, and whilst many failures are due to pressure surges, the condition of the oil is responsible for others. Failure is so much more frequent than one would anticipate with this type of plant, that special attention and research is called for. Most breakdowns have the appearance of being due to pressure surges resulting in burning and charring of some of the units. The consequent carbonization of the oil has a widespread effect on the remaining elements, and this can be determined by measurement of the power factor. In almost all cases of failure so far experienced it has been found necessary to renew the whole of the elements. The actual conditions which prevail prior to breakdown are still somewhat obscure. It seems probable that some ionization of the air entrapped between the layers of dielectric may occur and thus originate the trouble.

Recent improvements in the materials and construction of condenser elements may have a marked influence on the life of this type of plant.

Leading engineering insurance companies have realized the importance of the oil question in connection with electrical apparatus, and have equipped special testing laboratories for this reason. Samples of oil are taken by the companies' surveyors at regular intervals and despatched for testing, and the results amply justify the expense and trouble entailed. It is found that about 7·6 per cent of oil samples fail to comply with the requirements of the British Standard Specification, which stipulates that the oil shall withstand a pressure of 30 kV when tested between two spherical electrodes 0·157 in. apart. In addition, some 8·0 per cent of the examples examined contain a considerable amount of sludge. It must be understood these figures relate to oil samples taken in the ordinary routine way from apparatus which is actually in service, and not to samples of new oil.

In connection with the selection of electrical plant, a great number of consumers and purchasers of plant are non-technical men who do not realize the importance of high efficiency. There is consequently a tendency for them to purchase largely on the basis of first cost. It is a simple matter to take into account the factors of first cost and efficiency, and every case should be considered on its merits. With the prevailing prices for electrical plant and electrical power, it would in most cases pay to install plant of higher efficiency than that usually employed. Such efficiency should be secured by using lower current and magnetic densities, and not by reducing air gaps to dangerous values. In addition to the direct saving resulting from decreased losses, such machines would have a higher overload capacity, be more reliable and, by reason of working at a lower temperature, would have a longer life. Engineers should therefore use their influence to educate purchasers along these lines.

HAMPSHIRE SUB-CENTRE: CHAIRMAN'S ADDRESS

By B. HANDLEY, Member.

(*Address delivered at* PORTSMOUTH, *17th October*, 1929.)

As this is the first meeting of the Hampshire Sub-Centre, I have thought that, in my Address as the first Chairman of the youngest outlying branch of the Institution, it might not be amiss to address my remarks chiefly to the younger members and Students of this Sub-Centre upon their outlook in entering upon their profession. Not only will the progress of the Institution in the future depend upon the Students of to-day, but these same Students must in time become the directing forces in the electrical world.

Those who are now taking up the profession of electrical engineering are entering a profession which is daily becoming of more and more importance in the life of the community. Therefore the necessity of right understanding on the part of those young men who will ultimately control the electrical world cannot be over-emphasized.

The first thing which must be realized is that we are engaged in a profession in which change and new ideas are constantly occurring.

The use of electricity in the service of mankind has grown up in very recent times and now plays a most important part in the civilized life of the community. This very recent growth is but an offshoot of the use of any kind of power, which again is a development only slightly older.

To visualize how very recent this mechanical age is, we must remember that railways are only about a century old, which means that very many people to-day have spoken to men who saw the first railways laid down. These railways were extended with great rapidity throughout the country, and traffic was so diverted to them that the roads became of minor importance. In the last quarter of a century we have seen the development of the internal-combustion engine almost completely mechanize road traffic, so that now the number of men engaged in road traffic exceeds the number engaged in rail traffic.

Again, mechanical haulage on tramways is a very recent development, but in this case the indications are that tramways have passed their zenith and that their place will to some extent be taken by the omnibus driven by an internal-combustion engine.

The telegraph and telephone, and, recently, wireless broadcasting, are other examples of progress and change.

All these changes are very rapid and, to a great extent, correlated. An improvement in one industry leads to improvement in others. As an example of how interrelated all these advances and changes are, we might consider the development of aviation. Flying as we know it to-day would be hardly possible had not the invention of the pneumatic tyre—in the first case for bicycles—made travelling at high speeds in motor cars possible. The motor car led to the development of the internal-combustion engine, which afterwards made flying possible.

As another example, we have to-day in all countries power supplies distributed from central points over large areas. Let us try to realize how difficult this distribution over large areas would be without the motor car, and especially without the telephone. Taking a local example, in this area we have from this city a distribution reaching nearly to the River Hamble in the west, to Bognor in the east, and to Petersfield and Midhurst on the northern side. The electrical energy generated in this city passes over mains belonging to different local authorities and companies, before reaching its point of use by the consumer. Imagine what would happen if we were without our present facilities, and an interruption occurred at some distant point. All the local engineer would know would be that the supply had ceased. I should imagine that his next step would be to mount a bicycle or horse, or to take a train if possible, to try to meet the engineer in the contiguous area to see if his supply were all right. Think of the time that would be lost before the trouble was located. Now, thanks to the telephone and motor car, connection is established quickly between the various engineers, their reports are received and motor transport enables the trouble to be tackled at the earliest possible moment.

I merely mention these points as an indication to the young engineer how recent and how interrelated are all these mechanical and electrical services as we see them to-day. They are not only very recent but also in a continual state of change—not revolutionary changes, but quiet evolutionary changes, small in themselves, yet having remarkable effects in the aggregate.

In electrical engineering, as compared with engineering in general, we have perhaps an even more rapid change. The first transmission of power by electricity took place not many years ago. The first generating stations were started on extremely small lines, and were developed, in the light of our present-day knowledge, very slowly, until our accumulated knowledge and experience were such as to lead to improvements which developed the use of electrical energy in such strides as could not have been dreamed of many years ago. To-day the majority of our generating stations either have been built since the War, or at any rate use only machinery installed since the War.

Even our theories have in like manner gone through the same process of rapid evolution in such a way as to bear little resemblance to those of not very long ago. These theories, having served their purpose for the time, are superseded to make room for others.

I would therefore impress upon the young men to remember all the time that their knowledge, their theories, and their machinery must be in a state not only of change but of rapid change. When they see a power station built on the most modern lines, they must not imagine for one moment that there is any finality about it. What is the last word to-day will not be the last word next year. Let them keep their minds open all the time for fresh ideas. I remember once being in the company of a man when some of his old generating plant was being broken up. He remarked how sad it was to see the end of his old friends. It would have been wiser, perhaps, to have expressed pleasure at having something better to take its place.

This change which I am trying to impress upon you is evident not only in the activities which I have mentioned, but everywhere. Therefore you must keep your minds open to assimilate new ideas.

Looking for a moment towards the future, we can visualize the possibility of a time when there will be a far more convenient method of obtaining mechanical and electrical energy than by the combustion of coal; and, just as to-day we can transmit very small amounts of energy by wireless transmission, so can we visualize the future transmission of energy sufficient to meet our requirements in home, factory or traction, without the use of cables or wires. For the benefit of those who are leading the campaign against overhead lines on the South Downs, I may add that I am afraid such wireless transmission of power will not happen in their lifetime.

Having impressed upon you the importance of keeping your minds fresh and of not ignoring avenues of progress other than your own, I want now to come to another point to which attention must be given.

In your work you will have to deal with problems which your knowledge will enable you to solve with accuracy, and you will have to deal with machinery or apparatus which can be relied upon to give the results desired; this brings me to that part of your work in which reliability and accuracy must be attained by other methods. I refer to what is for many the most important part of the engineer's work, namely his ability, not so much to do the work himself, as to get it done by others working under his orders. This ability to get work done does not wholly depend upon his knowledge or experience of how the work should be carried out. We often see, in fact, that the man who has been the cleverest pupil or student does not attain any great success in the profession which he takes up. This may be to some extent accounted for by the fact that the clever student gets into the habit of working out problems with great accuracy and logical deduction, and that those same principles cannot operate with accuracy in dealing with mankind.

We must therefore try to get as plain an understanding of how man carries out his work as we try to get an understanding of how a piece of machinery works. First of all, let us remember that a man—either a manual worker or a brain worker—does not act according to formulæ or a chemical equation. We must also try to realize his component parts, just as we study the component parts of any machinery in order to understand how the whole works. Any failure to realize the functions of the different parts will cause failure in the complete understanding of the whole.

In engineering one becomes accustomed to analyse the functions of machinery in this way, and we must, if we wish to deal with mankind without failure, bring something of the same analysis to bear.

An important point to remember is that although all members of the human race conform to some general plan, there are countless varieties. When we study a mass-produced motor-car, for example, we know all the rest of that make; but when we attempt a similar comparison of mankind we are met by failure. Each of us has a standard by which there is always a tendency to judge others, and that standard is different for each of us. This unconscious tendency leads, unfortunately, to many mistakes and misunderstandings. Misunderstandings lead to irritation and strife, with consequent waste of energy, and to inefficiency, which every engineer must guard against, not only in his machinery but in the control of labour.

In trying to analyse man, we must remember that he is the product of countless ages of evolution. There must be in him many inborn, inherited instincts and all kinds of traits impressed upon him through the past ages. During the most recent part of his evolution there has grown up a civilization, learning and organized thought, so that to-day man has available the accumulated knowledge of the past, together with methods of organizing his thoughts for the acquirement of fresh knowledge. He has gradually learnt to think things out for himself, to put his proofs to the test, and to use his brain for considering what he needs and then inventing a method of supplying those needs. But all the time, and however efficient may be the brain power of any individual, we must remember the fundamental fact that the brain power is being operated by a child of countless ages with, to some extent at least, the impressed traits of those past ages, some of which crop out in one individual and some in another, but seldom exactly the same ones in different individuals.

You all know of otherwise intelligent people refusing to do things on Fridays, or to sit down 13 in number to a meal. Argue as you will, you will not dismiss that belief from the minds of those holding it. There is nothing extraordinary in this; it is merely the inherited instincts of the past, perhaps in this case the dread of the unknown, coming to the fore against the forces of their reasoning power.

I have even heard of a woman taking a violent dislike to another woman because she is wearing a hat of which the former does not approve. Again, illogical and absurd as it may seem to anyone trying to reason it out, there is nothing extraordinary about it. I can well imagine one of her forebears in the distant past coming across one of another tribe whose appearance offended him. As I believe that it was the custom in those days to walk about with a heavy club in one's hand, the result of the encounter can well be imagined.

Therefore I do impress upon you young engineers that you must not for a moment imagine that a man is a calculating or thinking machine. Any treatment based on that assumption is disastrous.

You must look upon human beings, including yourselves, as having all the foibles and inconsistencies which are our inheritance and the inevitable consequence of our evolution from the animal world.

You will never be able to get work done efficiently and cheerfully if you have any misconception on this point or if you fail to give consideration to the ideas and thoughts of those with whom you have to work. However absurd you may think the whims and ideas of others, yours may be considered by them to be equally absurd.

You must make allowances for all the seemingly inexplicable inconsistencies and uncalled-for irritation which man at times shows, remembering all the time that there is a reason for it, just as there is a reason for everything that happens, and if you can only ascertain the reason you are well on the way to remove the irritation.

You have to accept the state of things as they are, however inconvenient they may be for efficient working.

The final point which I wish to bring forward is that all engineering processes must have a commercial aspect. It is possible to do quite a number of engineering jobs which cannot be justified commercially, but if they cannot be justified in this way it is better not to do them. If a bridge has to be built it should be justified by the traffic that it will carry. If new machinery is to replace old machinery, the saving in the cost of running the new machinery must more than counterbalance the cost of installing it. Some things such as drainage systems, for instance, are justified by the results accruing to the community, results to which it is difficult to assign a money value, and in any case a broad view has to be taken in considering these problems. For instance, it is difficult at times to persuade a factory owner to electrify his plant if he considers only the cost of the power and will not take account of the fact that electricity will result in a bigger output per employee, which is often more valuable to him than the total cost of the power.

In conclusion I should like to say that the young electrical engineer of to-day is entering a profession which seems likely in a short time to be essential at almost every hour of the day to the inhabitants of large cities. You can look forward to the time when the mechanization and, I might add, the electrification of our activities in the home, office and factory, will be increased to a still greater degree, with a lightening of the housewife's burden and a greater output per man and greater earning power in the factory, with less exertion and more opportunity for recreation. You young men will also be able to look forward to our towns becoming cleaner and healthier by your activities, and possibly to the time when the burning of raw untreated coal will be a criminal offence.

There is still, in spite of all that has recently been accomplished, much work to do, and in rendering your services to the community I trust that the community will properly discharge the debt it will owe to you.

PROCEEDINGS OF THE INSTITUTION.

790TH ORDINARY MEETING, 24TH OCTOBER, 1929.

Lieut.-Col. K. Edgcumbe, T.D., R.E.T. (Ret.), Past-President, first took the chair, at 6 p.m.

The minutes of the Annual General Meeting and of the Special General Meeting, both held on the 9th May, 1929, were taken as read and were confirmed and signed.

A list of candidates for election and transfer, approved by the Council for ballot, was also taken as read and was ordered to be suspended in the Hall.

The Chairman announced that during the period April–September, 585 donations and subscriptions to the Benevolent Fund, amounting in the aggregate to £504, had been received.

The Premiums (see vol. 67, pages 808 and 1064) and Scholarships and Grants (see vol. 68, page 83) awarded during the past session were presented by the Chairman to those recipients who were present.

The Chairman then drew the attention of the meeting to the arrangements made by the Engineering Department of the Post Office for the simultaneous transmission of the proceedings to special local meetings of members at Birmingham, Cardiff, Glasgow, Leeds, Liverpool, Manchester, Newcastle-on-Tyne, Portsmouth and Southampton, where loud-speakers had been installed enabling speech from any one point to be reproduced at all the other points. A " roll-call " of these meetings was taken, Colonel Edgcumbe calling upon each Chairman in turn to announce whether the meeting was in session; and the responses, which were all received in the affirmative, were reproduced in the Lecture Theatre by means of loud-speakers.

The Chairman then sent greetings on behalf of those present in London to the members of the Local Centres and Sub-Centres at the towns indicated above.

Mr. W. B. Woodhouse: It is 12 months since we met to welcome a new President. To-day we are here on the same business, and we have to say good-bye to the President whom we greeted last year. He now retires into the obscurity which is supposed to surround past-presidents, but I am sure from his activity in the past that, like some other past-presidents whom I see here, he will continue to take an active part in the Institution which he loves. I am sure that you will not wish to let this occasion pass without expressing your appreciation of the manner in which Colonel Edgcumbe has performed his duties. In representing the Institution publicly, and in particular during the Summer Meeting, he worthily upheld the traditions of the Institution. His conduct of the meetings and of the public business of the Institution needs no word of praise from me. Those of us who are on the Council have seen much more of the work that falls upon the President's shoulders. In Council and in Committee he has continued the good work which he has been doing for many years. He was not, if I may say so, elected President merely because he was so charming and because of his fluency and his humour, but because we knew by experience that he was deeply interested in every activity of the Institution and that he was anxious to help to keep our great organization to the fore. I am sure that those who have served with him on the Council appreciate very much his great energy and his great ability. We are sorry to lose him as President, but we are very glad to know that we shall still have him as a past-president. I have pleasure in moving a formal resolution: " That the best thanks of the Institution be accorded to Lieut.-Col. Edgcumbe for the very able manner in which he has filled the office of President during the past year."

Captain J. M. Donaldson: It is a very great honour to be asked, as I have been, to second the resolution which has just been moved by Mr. Woodhouse. I am lucky in having to follow him, because he has said, much better than I myself could have done, what I feel very strongly. There is no doubt at all in my mind, and I am sure that there can be none in yours, that Colonel Edgcumbe has worthily carried on the traditions of the office, and that he has in every way enhanced the dignity of the position. He has certainly made a reputation second to none in his after-dinner speeches. I have very much pleasure in seconding the resolution.

The resolution was then put to the meeting and was carried with acclamation.

Lieut.-Col. K. Edgcumbe: It is very pleasant to be thanked for what one has done, even if one has not done it, but what with four energetic vice-presidents, a Council that overlooks all one's shortcomings, and a most efficient Secretary and staff, the President's job is a very simple one. I have to thank the members firstly for the trust which they reposed in me by electing me their President, and then for having backed me up so wholeheartedly as they have done. I feel particularly grateful to the Centres and Sub-Centres, and should like to take this opportunity (one which has not come to any past-president previously) of thanking them personally and simultaneously for their hospitality and for the many pleasant hours which I have spent with them. I would add that I think we members in London have much to learn from the Local Centres as to the way in which they conduct their affairs. I cannot refrain from drawing attention to the new decorations and improved lighting of the Lecture Theatre which I am sure you will agree is equal to, if not better than, that of any similar building in London. The colour scheme is, of course, the work of the Institution's architects, Messrs. Adams, Holden and Pearson, but we are also much indebted to Mr. C. C. Paterson and Mr. H. T. Young for the large amount of time, trouble, and skill which they have given to devising this very successful blending of decoration and illumination.

The chair was then vacated by Colonel Edgcumbe and taken by **Colonel Sir T. F. Purves, O.B.E.,** President, amid applause.

The President then delivered his Inaugural Address (see page 1), at the conclusion of which Colonel Edgcumbe called in turn on Mr. J. Harcourt Williams to propose, from Manchester, and Prof. Magnus Maclean to second, from Glasgow, a vote of thanks to the President for his Address.

Mr. J. Harcourt Williams in proposing the vote of thanks, said: " On such a unique occasion as this when the President's Inaugural Address has been broadcast to the Local Centres and Sub-Centres, one is deeply sensible of the privilege that now falls to the Local Centres for the first time, of proposing and seconding a vote of thanks to him for his Address. May this not be the beginning of a new era, when we shall have papers read in London with members at the Local Centres taking part in the discussion? As one who has had to deal chiefly with the heavy side of engineering, I can only express admiration for the President's very clear and interesting review of progress in electrical communications since 1922—progress that has been very real and great. I am impressed by that part of his Address which deals with education, and by his sound remarks on the training of engineers. His plea is that they should be trained in such a way that they will know how to use their brains when, having left college, they find in actual practice the necessity of specializing. The use of automatic telephone apparatus in the Post Office has its counterpart in automatic gear in other branches of electrical engineering, with the same object of reducing the cost of labour and the consequent cost to the user. Again, the President's reference to the remarks of Mr. Frank Gill before this Institution in 1922, on long-distance telephony, makes us very conscious and proud of the influence exerted by our Institution all over the world. We can infer from what our President has said, that it must now have a great influence in maintaining the peace of the world, a very understandable and desirable effect. It also has, naturally, great commercial possibilities, and I know of one case where a firm, with interests on both sides of the Atlantic, holds conferences by telephone between their respective organizations collected round a table at each end of the line. I now have formally to move: 'That the best thanks of the Institution be accorded to Colonel Sir Thomas Purves for his interesting and instructive Presidential Address, and that with his permission the Address be printed in the *Journal* of the Institution.' "

Prof. Magnus Maclean, in seconding the vote of thanks, said: " I have great pleasure in seconding the motion so happily and appropriately proposed by Mr. Harcourt Williams at Manchester. The Address was heard here in Glasgow quite distinctly and the members present highly appreciate the choice of subject and the masterly way in which the President has treated it. The novelty of this meeting recalls to my mind that of another occasion, in the year (1902) when our President joined the Institution. It was our first Annual Dinner in the Windsor Hotel, Glasgow, and I had the honour of presiding. The novelty, I remember, evoked considerable curiosity and speculation at the time. Attached to the lighting brackets and hidden by greenery were arranged a number of loud-speakers connected to a transmitter in a room of the telephone exchange, nearly half a mile away. In that room was stationed a band which rendered solos and accompaniments in connection with the loyal toasts—the music of which was heard in the dining hall of the hotel with a clearness and distinctness which was thought extraordinarily remarkable and even eerie at that time, 27 years ago. Four years earlier when Marconi established stations to communicate between the Isle of Wight and Bournemouth, Lord Kelvin made his way to the Needles station and, sending a message by way of test, insisted on paying for it as evidence of his faith in the ultimate success of wireless communication as a commercial enterprise. He was thus the first person in the world to send a paid 'marconigram' and, as the message was for me, I was the first to receive one. We have travelled far since then, as the address and our programme this evening show. The author of Ecclesiastes has said: 'God hath made man upright; but they have sought out many inventions.' Man is at his old tricks—his feats of ingenuity, worse or, shall I say, more determined than ever to-day. But we no longer condemn. On the contrary, we cannot honour enough the men who, like our President, 'put girdles round the earth' in a way that even Shakespeare himself never envisaged. Puck, on the wings of imagination, could encircle the world in 40 minutes. It can now be done, as we all know, in the fraction of a second. I second the resolution with the cordial approval of all members of the Scottish Centre. 'Oidche mhath leibh, beannachd leibh.' "

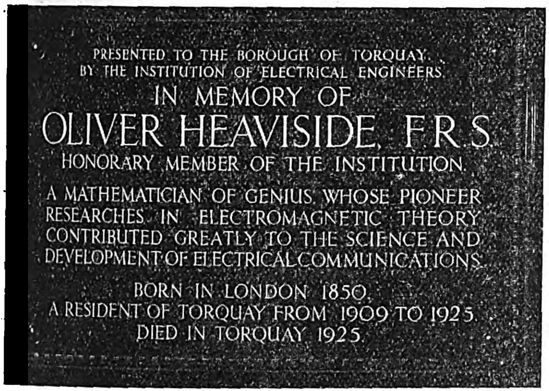
The resolution was then put to the meeting by Colonel Edgcumbe, Past-President, and was carried with acclamation.

After the President had briefly replied, the meeting terminated at 7.25 p.m.

INSTITUTION NOTES.

Oliver Heaviside.

The Institution recently presented to the Borough of Torquay a bronze tablet for erection in the Town Hall in memory of the late Oliver Heaviside, F.R.S., who was an Honorary Member of the Institution and died at Torquay in 1925. A photograph of the tablet is reproduced below.



PRESENTED TO THE BOROUGH OF TORQUAY
BY THE INSTITUTION OF ELECTRICAL ENGINEERS
IN MEMORY OF
OLIVER HEAVISIDE, F.R.S.
HONORARY MEMBER OF THE INSTITUTION.
A MATHEMATICIAN OF GENIUS WHOSE PIONEER
RESEARCHES IN ELECTROMAGNETIC THEORY
CONTRIBUTED GREATLY TO THE SCIENCE AND
DEVELOPMENT OF ELECTRICAL COMMUNICATIONS.
BORN IN LONDON 1850.
A RESIDENT OF TORQUAY FROM 1909 TO 1925.
DIED IN TORQUAY 1925.

Alterations to Bye-Laws.

The amendments to the Bye-laws agreed upon at the Special General Meeting held on the 9th May last have been allowed by the Privy Council.

Kelvin Medal.

The fourth triennial award of the Kelvin Medal has been made by the Joint Award Committee to Monsieur André Blondel.

Scholarships.

The following Scholarships have been awarded for 1929–1930:—

Salomons Scholarships (*value* £50 *each*).

R. B. Smith (Leeds University).
F. W. L. Horner (Belfast Municipal Technical College).

David Hughes Scholarships (*value* £50).

P. F. Soper (East London College).

Paul Scholarship (*value* £100).

K. H. Gillanders (L.C.C. Brockley County School).

War Thanksgiving Education and Research Fund (No. 1).

Grants of £50 each have been made for 1929–1930 to the following for research purposes:—

J. A. Clegg (University College, London).
A. F. Wilkins (Cambridge University).

Page Prize.

The Page Prize (value £2 10s.) has been awarded for the session 1928–1929 to Mr. R. Woodland for a thesis entitled " The Cryptophone."

" Science Abstracts."

The Council have decided to supply *Science Abstracts* to Students, and to Graduates under the age of 28, at a nominal annual subscription of 5s. for either the Physics or the Electrical Engineering Section, or of 7s. 6d. for both Sections. Full particulars are being sent by the Secretary to these members.

Graduates.

Under the revised Bye-laws, Graduates under the age of 28 years are entitled to the same privileges as Students, i.e. attendance at all Institution Meetings (including those of the Students' Sections), visits to works and social functions included in the Students' programmes.

National Certificates and Diplomas in Electrical Engineering (England and Wales).

The undermentioned colleges have been approved under the scheme drawn up by the Board of Education and the Institution:—

Approved for Ordinary Grade Certificates (*Senior Part-time Course*).

Barrow-in-Furness Technical College.
Croydon Polytechnic.

Approved for Higher Grade Diplomas (*Advanced Full-time Course*).

Nottingham University College.

Discussions at Meetings.

The Council wish again to remind members that the remarks of speakers at the meetings should not be read from manuscript, the view being held that the presentation of remarks in this manner is contrary to the true spirit of a " discussion " and that contributions in manuscript should more appropriately be sent to the Secretary for publication in the *Journal* as " communicated remarks."

Benevolent Fund.

An appeal to members to support the Fund will be found on the last page of the cover of this issue of the *Journal*.

Committees, 1929-30.

Among the Committees appointed * by the Council for 1929–1930 are the following:—

INFORMAL MEETINGS COMMITTEE.

Mr. E. S. Ritter (*Chairman*).

Mr. J. R. Bedford.
Mr. W. E. Bradshaw.
Mr. R. Grierson.
Mr. W. Lang.
Mr. A. Morgan.
Mr. C. F. Mounsdon.
Mr. W. A. Ritchie.
Mr. W. E. Rogers.
Mr. M. Whitgift.

And

A representative of the General Purposes Committee.
The Chairman of the Papers Committee.
The Chairman of the London Students' Section.

JOINT COMMITTEE FOR NATIONAL CERTIFICATES AND DIPLOMAS IN ELECTRICAL ENGINEERING (ENGLAND).

Mr. W. E. Highfield Prof. E. W. Marchant, D.Sc. Mr. W. M. Selvey	representing the I.E.E.
Dr. F. T. Chapman Dr. A. Morley Dr. C. F. Smith	representing the Board of Education.

JOINT COMMITTEE FOR NATIONAL CERTIFICATES AND DIPLOMAS IN ELECTRICAL ENGINEERING (SCOTLAND).

Prof. G. W. O. Howe, D.Sc. Mr. S. Mavor Mr. Robert Robertson, B.Sc. Prof. S. Parker Smith, D.Sc.	representing the I.E.E.
Dr. J. S. W. Boyle Mr. J. G. Frewin Mr. W. Hyslop Mr. F. W. Michie	representing the Scottish Education Department.

LIBRARY AND MUSEUM COMMITTEE.

Col. R. E. Crompton, C.B.
Mr. D. N. Dunlop, O.B.E.
Capt. C. E. Kennedy-Purvis, R.N.
Mr. W. M. Mordey.
Mr. D. S. Munro.
Mr. R. S. Whipple.

LOCAL CENTRES COMMITTEE.

Mr. J. R. Beard, M.Sc.
Capt. J. M. Donaldson, M.C.
Mr. J. S. Highfield.
Mr. P. V. Hunter, C.B.E.
Mr. Archibald Page.
Mr. E. E. Sharp.
Lt.-Col. W. A. Vignoles, D.S.O.

And the Chairman of each Local Centre and Sub-Centre.

METER AND INSTRUMENT SECTION COMMITTEE.

Mr. E. W. Hill (*Chairman*).

Mr. W. E. C. Alliss.
Mr. E. Fawssett.
Mr. C. H. W. Gerhardi.
Mr. A. J. Gibbons.
Mr. J. T. Haynes.
Mr. F. C. Knowles.
Mr. C. W. Marshall, B.Sc.
Mr. A. Middleton.
Mr. E. H. Miller.
Mr. W. Phillips.
Mr. G. F. Shotter.
Mr. R. S. J. Spilsbury.

And

A representative of the Council.
The Chairman of the Papers Committee.

"SCIENCE ABSTRACTS" COMMITTEE.

Mr. T. G. N. Haldane, M.A.
Prof. E. W. Marchant, D.Sc.
Mr. W. M. Mordey.
Mr. C. C. Paterson, O.B.E.

Dr. A. Ferguson Dr. D. Owen	representing the Physical Society of London.

SHIP ELECTRICAL EQUIPMENT COMMITTEE.

Mr. A. G. S. Barnard.
Major B. Binyon, O.B.E., M.A.
Mr. J. H. Collie.
Mr. S. Harcombe, M.A., B.Sc.
Mr. A. Henderson.
Mr. P. V. Hunter, C.B.E.
Mr. J. W. Kempster.
Mr. J. F. Nielson.
Mr. N. W. Prangnell.
Col. A. P. Pyne, R.A. (T.A. Res.).
Mr. S. G. C. Russell.
Mr. T. A. Sedgwick.
Mr. H. D. Wight.
Mr. E. T. Williams, O.B.E.

And	*Representing*
Mr. A. E. Laslett, I.S.O. Mr. W. McAuslan	Board of Trade.
Mr. W. Cross	Electrical Contractors' Association.
Mr. J. Carnaghan Mr. H. Ruck Keene	Lloyd's Register of Shipping.
Mr. James Barr Mr. T. R. Thomas	British Corporation for the Survey and Registry of Shipping.
Mr. J. Lowson	Institution of Engineers and Shipbuilders in Scotland. Electrical Contractors' Association of Scotland.
Mr. A. W. Stewart	Institution of Naval Architects.
Mr. W. T. Wilson	N.E. Coast Institution of Engineers and Shipbuilders.

WIRELESS SECTION COMMITTEE.

Captain C. E. Kennedy-Purvis, R.N. (*Chairman*).

Mr. R. H. Barfield, M.Sc.
Mr. F. W. Davey.
Mr. A. J. Gill, B.Sc.
Mr. J. Hollingworth, D.Sc., M.A.
Lt.-Col. A. G. Lee, O.B.E., M.C., B.Sc.
Prof. E. Mallett, D.Sc.
Mr. E. B. Moullin, M.A.
Mr. G. H. Nash, C.B.E.
Mr. L. C. Pocock.
Mr. C. E. Rickard, O.B.E.
Commander J. A. Slee, C.B.E., R.N.
Mr. P. K. Turner.

A representative of the Council.
A representative of the General Purposes Committee.
The Chairman of the Papers Committee.

And the following representatives of Government Departments:

Admiralty: Capt. C. E. Kennedy-Purvis, R.N.
Post Office: Lt.-Col. A. S. Angwin, D.S.O., M.C.
Air Ministry: Mr. F. S. Barton, M.A., B.Sc.
War Office: Major J. S. Yule, O.B.E., R.C.S.

---

* The President is, *ex officio*, a member of all Committees of the Institution.

Wiring Regulations Committee.

Mr. Ll. B. Atkinson.
Mr. W. J. Bache.
Mr. H. J. Cash.
Mr. J. R. Cowie.
Col. R. E. Crompton, C.B.
Mr. B. M. Drake.
Mr. P. Good.
Mr. R. Grierson.
Mr. J. F. W. Hooper.
Mr. H. Marryat.
Mr. S. W. Melsom.
Mr. F. W. Purse.
Col. A. P. Pyne, R.A. (T.A. Res.).
Mr. E. Ridley.
Commander J. A. Slec, C.B.E., R.N.

And	*Representing*
Mr. J. Howard-Blood	Fire Offices Committee.
Mr. E. B. Hunter ..	
Mr. W. B. Trafford ..	
Mr. E. G. Batt ..	British Electrical and Allied Manufacturers' Association.
Mr. H. H. Berry ..	
Mr. J. R. Dick, B.Sc.	
Mr. A. R. Everest ..	
Mr. F. Broadbent ..	
Mr. W. F. Bishop ..	Cable Makers' Association.
Mr. F. R. Baldock ..	Independent Cable Makers' Association.
Mr. W. R. Rawlings	Electrical Contractors' Association.
Mr. E. A. Reynolds	
Mr. R. A. Ure ..	Electrical Contractors' Association of Scotland.
Mr. C. G. Morley New	Incorporated Municipal Electrical Association.
Mr. R. W. L. Phillips	
Mr. W. Lang ..	Association of Supervising Electrical Engineers.

Thornton, W. M., *O.B.E.*, *D.Sc.*, *D.Eng.* Notes on the electrical transmission of energy. A survey of the physical basis of electrical transmission, its methods and phenomena from the standpoint of the electron. 2nd ed. sm. 8vo. 132 pp. *London*, 1929

The 1st ed., published 1921, *has title* "First principles of the electrical transmission of energy."

White, W. J. Questions and solutions in magnetism and electricity. Consisting of solutions to the questions set by the Board of Education and City and Guilds of London Institute in Stage I of Magnetism and Electricity during 1907–1929. 3rd ed. 8vo. 185 pp. *London*, 1929

Wilson, P., *M.A.*, and Webb, G. W. Modern gramophones and electrical reproducers. 8vo. 288 pp. *London*, [1929]

Winzheimer, R. Übertragungstechnik. 8vo. 239 pp. *München*, 1929

World Power Conference. Power resources of the world. (Potential and developed.) Preface by D. N. Dunlop. 8vo. 182 pp. *London*, 1929

Revised Bye-laws and Membership Changes.

The following transfers * have been effected by the Council in accordance with the provisions of Bye-laws 15 and 18:—

From Graduate to Associate.

Abaza, Mohammed Shoukry H.
Acock, Charles Edward.
Acomb, Frank.
Addison, Joseph.
Adie, Brooke.
Aggarwala, Harish Chandra.
Ahaluwalia, Rakharam.
Aiyar, Aiyalam Kasturi R. K.
Aked, W. T.
Aldridge, Percy Spencer.
Alford, Frederick Albert H.
Ali, Mir Laig.
Allan, John Edward.
Allen, Edward.
Allen, James.
Allington, Ernest.
Allkins, Arthur Warrington.
Allsop, David.
Alston, Basil Evelyn.
Ambalavanar, Pasupathippillai.
Amies, George.
Anderson, David Bruce.
Anderson, Herbert.
Andrews, Harold Arthur.
Ansell, A. M.
Appleby, John Harry.
Armstrong, Stanley Ignatius.
Armstrong, William Henry.
Arnold, John Frank.
Arnold, Louis.
Arnott, John Thomson.
Arnott, J. W.
Arte, Dattatraya Bhaskar.
Arthur, Austin Bassett.
Aspin, John.
Astley, Harold.
Aston, Walter.
Athaide, Lewis Michael.
Atkins, Leslie John.
Atkinson, Joshua Percy.
Atkinson, Raymond.
Attwood, Albert Henry.
Aust, Octavius Leonard Genge.
Avis, William John.
Avison, Robert Geoffrey.
Ayres, Talbot Martin.
Ayyar, Paghayannar Venkiteswara S.
Aziz, Jan Mohamed A.
Badhni, Jehangirshaw N.
Baggaley, Cyril Frank.
Bailey, Albert Clifford.
Bailey, Alfred.
Bailey, Arthur Rowland.
Bailey, F.
Bailey, John Wallis.
Bailey, Walter Horace.
Baillies, Douglas C.
Baker, Charles Hale.
Baker, William Frederick.
Balasubramian, M. S.
Balchin, Wilfrid George.
Baldock, G. J.
Baldwin, Douglas.
Baldwin, Norman Victor.
Ball, Wilfred Charles D.
Bamji, Hormusji Fardoonji.
Bancroft, Herbert Douglas.
Banerjee, Aswini Kumar.
Banerji, Srish Kumar.
Banks, Albert.
Banks, T. H.
Barkwith, Joseph William B.
Barnacle, Alfred B.
Barnes, Wilfred Charles.
Barnett, Reginald Hugh.
Barrand, Percy Christian.
Barrar, Sydney John.
Barrell, Frank.
Barry, Gerald Noel F.
Bartels, D.
Bartho, Francis Trenam.
Barton, Leslie Osborne C.
Basil, Bishen Duo.
Bassett-Lowke, Harold Austin.
Batten, Ernest Richard.
Baverstock, Charles James.
Baxendell, Leslie Wilfred E.
Baxter, Frank Sladdin.
Baxter, William Morley.
Beaglehole, Keith.
Bealing, Ernest.
Beaton, Cecil Arthur.
Beaumont, Leonard.
Bechar, Shivji.
Beddall, Walter Samuel H.
Bedford, Howard Edwin.
Bedford, Reginald.
Bee, Oswald Kestor.

---

* A list of transfers from Associate to Companion will be published in a later number of the *Journal*.

From Graduate to Associate—continued.

Beebee, Arthur Thomas S.
Beeston, Harold Chas.
Belchem, Robert Henry.
Bell, Cyril Gordon.
Bell, Edgar David R.
Bell, Herbert Harry.
Bell, Hubert Vaughan D.
Bell, Ian.
Bennett, Arthur Edgar.
Bennett, Henry Percy.
Bennett, Wilfred.
Berg, Clement Leonard.
Beringer, Paul.
Bernard, Sattambisallage Don.
Berry, Edgar.
Berry, Jack Milton H.
Berry, John.
Betley, John Ernest.
Betts, Arthur George.
Beynon, Benjamin Thomas
Bhargava, Govadhan Prasad.
Bhargava, Har Saran D.
Bhise, Vishwanath Ramchandra.
Bickerstaff, Ernest.
Bickerton, Harry.
Bill, Ronald Archie.
Billingsley, Frederick Thomas.
Billingsley, Reginald Harry.
Bintley, Bryan Noel.
Birch, Ewart Evelyn.
Birkby, Harold.
Black, E. J.
Black, Richard Henry.
Blackburn, Harry Arthur.
Blackler, Clarence William.
Blakeley, Wilfred John.
Blashill, T.
Bleasdale, John William.
Bloemsma, Jan.
Bloome, Jack.
Bloore, Thomas Addison.
Boak, C. F.
Boddington, Frank Stanfield.
Bogie, Andrew.
Boiston, Alfred.
Bolton, E. S.
Bolus, John Edward.
Bond, Fred.
Bonn, Arthur Stanley.
Bonny, Arthur Geo. A.
Booth, Clifford.
Boscolo, Gioachino Riccardo.
Bostock, Clement Wildsmith.
Bourn, Leslie Edwin A.
Bourne, George.
Bowden, Lionel Maurice.
Bower, Dudley Alec.
Boyce, John Samuel.
Boyd, William John.
Bradford, Wilfred Brittain.
Bradley, Robert Walter.
Braggins, Albert Edward.
Brammer, Cyril George.
Brander, J.
Brant, William.
Brazier, Cyril James H.
Brewer, Arthur.
Briant, Frederick Gordon.
Brickhill, George Alexander.
Brierly, Richard Francis H.
Briggs, Bernard George.
Briggs, Richard Alfred.
Bristow, Ralph Eric.
Brocklebank, John.
Brockway, Cyril Hotston.
Brooks, John.
Brooks, John Joseph.
Brough, Leonard George.
Brown, David Gregory.
Brown, Edward.
Brown, Edwin Lionel.
Brown, Eric James W.
Brown, Frank Leader.
Brown, George Victor.
Brown, Hugh, Junr.
Brown, Robert Hartley C.
Brown, William Herbert.
Brown-Stephens, Charles.
Bruce, George Lance.
Bruce, Herbert Baillie.
Bruce, James Malcolm.
Bruce, Robert Francis.
Bryan, Francis Charlton.
Bryant, Frank.
Bryant, Roger Havelock.
Buchanan, George Macdonald.
Buchanan, Joseph.
Buckell, Victor Charles H.
Buckland, Bert.
Buckley, Joseph Duckworth.
Budge, James Walker.
Bull, Arthur John.
Bull, Robert.
Bull, Walter John H.
Bulley, Henry Samuel.
Bulman, Christopher Howard.
Bulman, George Reay.
Bunt, Charles Lionel.
Burcham, Leonard Walter.
Burford, Gerald George.
Burgess, William.

From Graduate to Associate—continued.

Burn, Walter.
Burns, John.
Burnett, Robert Ernest S. F.
Burton, Edward Arthur.
Bushell, John David.
Butler, Archibald Stephen.
Butler, William Richard.
Butterfield, Edwin.
Cadman, Horace Bert.
Cadman, Norman.
Calder, John Maxwell.
Calver, Frank Norman.
Cameron, Alexander Robert.
Cameron, William Charles.
Campbell, Archibald Stewart.
Campbell, Duncan.
Campbell, James Philip.
Campbell, Percy Oliver.
Caplin, William John.
Capper, Frank Wilton.
Carey, Hewett Clive.
Carlisle, Ralph Sydney.
Carr, Conway Buxton.
Carter, Ernest.
Carter, Frank.
Carter, Frank Alexis.
Carter, Gordon Leonard.
Carter, William.
Cass, Vernon Sydney.
Catford, Edwin Osmond.
Catton, Horace William.
Causbey, Reginald John.
Cerexhe, F. G.
Chakravarti, Girindra Narayan.
Chakravarti, Nripendranath.
Chalmers, John Wm. P.
Chamen, William Francis.
Chandler, A. F. N.
Chaplin, Walter Richard.
Chapman, Alfred Herbert.
Chapman, Eric Douglas S.
Chapman, Robert Frederick.
Charlton, Charles Cedric.
Charlton, Edward.
Charman, Cyril Edward.
Chase-Currier, Victor Charles.
Chauhdri, Ghulam Kadir.
Chayachati, Svasti.
Chester, William Haward.
Chesterton, Arthur James.
Chopra, Hukm Chand.
Christie, John Mills.
Churchill, Charlie Hembrow.
Churchill, Percy.
Clare, Charles Frederick.
Clark, Ernest Cameron.
Clark, Geo.
Clark, John Thomas.
Clarke, Albert Edward.
Clarke, Albert Stanley.
Clarke, Edgar Valentine.
Clarke, William Henry.
Clarricoate, John.
Clayton, C. E.
Clayton, William Henry.
Cleary, Herbert.
Clements, Henry.
Clewett, William Henry.
Clifford, Leonard Percy.
Clifford-Jones, Edward Thomas.
Clissold, William Cornelius.
Cobb, Frederick Arthur.
Cochran, Robert Jack.
Cockburn, Roland Arthur.
Cockerill, Henry Walter.
Coffee, Randall.
Colaco, Julian Antony.
Coldwell, David Kidd.
Cole, Henry James C.
Collard, Herbert William.
Collett, J. W.
Collier, Harold.
Collins, Herbert.
Collins, Thomas Lewis.
Collom, Frederick William.
Collyer, James Kimberley.
Colquhoun, James Browne
Condé, Harold Graydon.
Constable, Leslie Stuart.
Conville, Alfred.
Conway, George Harold.
Cook, Ernest Henry.
Cook, E. T.
Cook, John.
Cooke, Maurice Wyndham.
Cooke, Ralph.
Cooney, Alexander Patrick.
Cooper, Arthur.
Cooper, Edward Cecil.
Cooper, George.
Cooper, George William.
Cooper, H.
Cooper, John Ashton J.
Cooper, Walter Dunbar.
Coote, Charles Douglas.
Corbett, Francis William J.
Corder, George Falconer.
Corkill, William Alfred.
Corner, Arthur Charles.
Corner, Herbert.
Cottier, John Percival.
Cound, Richard Aubrey.

From Graduate to Associate—continued.

Court, Arnold Frederick.
Coveney, Henry Percival R.
Cowan, Eric William L.
Cowen, Alan Biddulph.
Cowen, Arnold Benjamin.
Cox, Cecil Louis.
Cox, Percy Harold.

THE ANALYSIS AND MEASUREMENT OF THE NOISE EMITTED BY MACHINERY.

By B. A. G. Churcher, Member, and A. J. King, Associate Member.

(*Paper first received* 19*th December*, 1928, *and in final form* 5*th October*, 1929*; read before* The Institution 7*th November, before the* Western Centre 11*th November, and before the* North-Eastern Centre 9*th December*, 1929.)

Summary.

The paper deals with part of a comprehensive investigation which is being carried out by a manufacturer of electrical plant on the noise emitted by machinery and other apparatus, a subject of great present and future importance. The need for treating the subject in a thorough and quantitative manner for engineering purposes is pointed out. The physical magnitudes involved in the measurement of the sound set up by a vibrating body are discussed generally, together with the characteristics of the ear. The characteristics that should be possessed by a sound-measuring apparatus intended for use in engineering problems are pointed out and a brief survey is made of existing types of apparatus. The principle, development and final form of the apparatus, which enables a complete analysis of a complex sound to be made, are described, together with the methods employed to verify the accuracy of the apparatus. The influence of the conditions under which sound measurements on engineering apparatus are carried out is discussed, and a special laboratory which has been set up for acoustical work is described. Some sound-test results on engineering apparatus are given as examples.

Table of Contents.

List of symbols.
(1) Introduction.
(2) General considerations.
(3) The characteristics of the ear.
(4) Available sound-measuring apparatus.
(5) An electrical sound analyser.
  (*a*) General principle.
  (*b*) Considerations of the microphone characteristic.
  (*c*) No. 1 apparatus.
(6) Methods of calibration.
  (*a*) Intensity calibration.
  (*b*) Frequency calibration.
  (*c*) Effect of microphone dimensions on calibration.
(7) No. 2 apparatus.
  (*a*) Design.
  (*b*) Performance.
(8) Test-conditions for general sound measurements.
(9) Laboratory for acoustical work.
(10) Examples of test results.
(11) The assessment of total noise.
(12) Further fields for acoustical measurements.
(13) Conclusions.
Bibliography.

List of Symbols.

A = strength of sound source in terms of maximum rate of emission of fluid (cm^3 per sec.).
a = area of diaphragm (cm^2).
B = flux density (lines per cm^2).
β = elastic restoring force (dynes for 1 cm displacement).
K_1 = Rayleigh disc constant.
d = linear deflection on scale.
E = maximum instantaneous e.m.f. (volts).
e = R.M.S. volts.
F = damping resistance (dynes for velocity of 1 cm per sec.).
f = frequency, in cycles per sec.
I = current, in amperes.
θ = angle between normal to Rayleigh disc and axis of tube.
$K_2 = NB \times 2\pi r \times 10^{-8}$; also mA/mV/mH.
$k = \omega/v = 2\pi/\lambda$.
L = inductance.
d_1 = distance from scale to mirror.
l = length of suspension (cm).
λ = wavelength (cm).
M = mutual inductance (henrys).
m_t = total mass of diaphragm.
m = correction factor for microphone dimensions.
N = number of turns on coil.
P = maximum value of alternating air pressure.
p = R.M.S. excess pressure (dynes per cm^2).
R = electrical resistance (ohms).
r = radius (cm) of sphere surrounding source of sound or distance from centre of source to sound detector.
r = radius of disc.
r_0 = radius of source of sound (cm).
ρ = density of air.
S = microphone sensitivity.
$\mathbf{T}_\mathbf{R}$ = restoring torque, in dyne-cm per radian per cm.
$\mathbf{T}$ = torque (dyne-cm).
t = time (secs.).
v_d = velocity of translation of diaphragm (maximum).
v = velocity of sound in air (cm per sec.).
v_0 = velocity at 0° C.
V = maximum air velocity.
W = average power per cm^2 at surface of sphere surrounding source (ergs per sec. per cm^2).
x = displacement (cm).
x = ratio of thickness to diam. of Rayleigh disc.
x = fractional frequency change.
Z = impedance (ohms).
$\omega = 2\pi f$.

(1) Introduction.

The work described in this paper was initiated in September, 1926, by a company engaged in the manufacture of electrical plant, with the object of attacking in a thorough and comprehensive manner the problem of the noise emitted by motors. Apart from the question of particular motors which may be considered to be too noisy, a definitely higher standard in respect of quiet running in motors in general is greatly to be desired. Although the need for the reduction of noise in motors led to the initiation of this work, the noise problem arises in many other types of engineering apparatus. Examples are transformers and integrating meters for domestic use, large generators and converting plant, gears and other mechanical apparatus. The technique and measuring apparatus developed in connection with sound tests on motors are also directly applicable to the other classes of apparatus. A considerable amount of useful work has been done on geared turbo sets as well as on motors. The apparatus can also be used for the quantitative determination of the characteristics of loud-speakers. There are other applications, many of which are outside the normal activities of the company.

It is necessary to be able to assess the noise emitted by a machine, for two main purposes: (*a*) to ascertain whether the noise is in excess of that desirable or permissible according to some definite standard, and (*b*) to ascertain the cause of the noise with a view to modifying or reducing it.

It has been suggested that as it is ultimately the ear which judges whether a machine is excessively noisy or not, there is no advantage in employing elaborate apparatus to measure noise. That this is not the case can be shown by the following considerations. Suppose a person is asked to listen to a machine for purpose (*a*). If he merely says that the noise is or is not excessive, his judgment will satisfy no one but himself and he will be asked to be more explicit. To be more explicit he must consider the noise in the two aspects of pitch and intensity or loudness. The average unmusical person can only express his sense of the pitch of simple sounds by such terms as very low, low, high, very high and so forth. On the other hand, some musicians have a keen sense of absolute pitch and can judge the pitch of an isolated note to within a semitone, i.e. to within 5 per cent. That is, however, a rare accomplishment. Then in regard to the all-important question of loudness, the sense of loudness of simple sounds can only be vaguely expressed by saying that the sound is moderate, loud, very loud and so forth. In practice, the sounds emitted by machines are nearly always complex in character, that is, several pitches are present simultaneously. It is then usually very difficult to pick out the pitches of the several components unless a few are particularly prominent, and it becomes even more difficult to judge loudness.

Thus, while the ear is an exceedingly sensitive and discriminating detector of sounds, it cannot yield the quantitative information required for purpose (*b*). As with other engineering quantities, it is necessary to deal with sound on a basis of measurement in terms of a definite standard rather than on the basis of the opinions of individuals. While physical quantities must be the medium by which sounds are measured and represented, the physiological aspect of the matter, namely, the susceptibility of the average ear to sounds of different kinds, must be given due consideration. This is particularly important when considering limits for the sound it is permissible for a piece of engineering apparatus to emit. Such limits must, of course, be fixed with reference to the physiological effect produced by the sound, and in that sense the average ear constitutes the fundamental standard. Physical measurement is necessary, however, in order to obtain quantitative results, to eliminate the vagueness of individual judgment, and to analyse complex sounds. In common with other physical measurements, it is a great advantage if the results can be expressed in absolute units under clearly defined test conditions, rather than in arbitrary units associated with some particular test method or apparatus. If this is achieved, the use of different types of apparatus by different investigators does not prevent their results being compared.

(2) General Considerations.

The occurrence of sound involves the action of three elements, the sound generator, which is essentially a vibrating body, the transmitting medium and the sound detector. In the problem of noise measurement, the sound generator consists of the apparatus under test, the air is the transmitting medium, and the ear or the acoustic element of a sound-measuring apparatus constitutes the sound detector. Suppose the source of sound consists of a small sphere which pulsates (expands and contracts) with simple harmonic motion by a small amount above and below its mean radius. Suppose that the sphere is placed in infinite space and no other bodies are present. The pulsating sphere sends out simple harmonic pressure waves in all directions, the length of the waves being equal to $\lambda = v/f$, where v is the velocity of sound in air and f is the frequency of the pulsations. If a detector is placed in the sound field so that it may be acted upon by the incident pressure waves, the moving element of the detector, e.g. a diaphragm, will be set in vibration by the alternating air pressure. The amplitude of the vibration will depend on the distance separating the source and the detector; the greater the distance, the smaller is the amplitude.

Let r_0 be the radius of the sphere, ρ the density of the transmitting medium, and $v_{max.}$ the maximum value of the pulsating velocity of the surface of the sphere.

The velocity potential at a distance r cm from the centre of the sphere is given by *

$$\phi = \frac{r_0^2(1 - ikr_0)v_{max.}}{r(1 + k^2r_0^2)} e^{i[\omega t - k(r - r_0)]}$$

where $\omega = 2\pi f$

and $k = 2\pi/\lambda$.

The pressure at a distance r cm due to the pulsating sphere is

$$p = \frac{\rho d\phi}{dt} = \frac{\rho\omega r_0(kr_0 + i)v_{max.}}{r(1 + k^2r_0^2)} e^{i[\omega t - k(r - r_0)]}$$

---

* See Bibliography, (5), p. 121.

It is easy to show that the maximum value of this pressure, which oscillates with a frequency f, is

$$P = \frac{\rho\omega r_0^2 v_{max.}}{r\sqrt{[1 + k^2 r_0^2]}}$$

If we call A the strength of the source and define it as the maximum rate of emission of fluid from the source, $A = 4\pi r_0^2 v_{max.}$ cm^3 per sec.

The expression for P then becomes

$$P = \frac{A\rho\omega}{4\pi r\sqrt{[1 + k^2 r_0^2]}} = \frac{A\rho f}{2r\sqrt{[1 + k^2 r_0^2]}} \quad . \quad (1)$$

If r_0 is small compared with λ, then kr_0 is small and we have

$$P = \frac{A\rho f}{2r} \text{ dynes (max.) per cm}^2$$

In the case of transmission in air, the density ρ is 0·00122 gramme per cm^3 at 15° C. and 76 cm pressure.

$$\therefore P = \frac{0{\cdot}00061\,Af}{r} \text{ dynes (max.) per cm}^2$$

The velocity with which the disturbance is propagated from the source in air is given by

$$v = \sqrt{\left[\frac{\gamma Q}{\rho}\right]}$$

where γ = ratio of specific heats of air = 1·401, and
Q = pressure of the air, in dynes/cm^2.

It follows from this relation that the velocity is independent of the air pressure (since $Q \propto \rho$).

It is also easy to show that the variation in velocity with temperature is given by

$$v = v_0 + 61t$$

where v_0 = velocity at 0° C. = 33 130 cm per sec.
and t = temperature of the air, in deg. C.

For t = 15° C., therefore, v = 34 050 cm per sec.

Referring to equation (1) it is seen that as one moves away from the source the sound pressure varies inversely as the distance from the centre of the source.

The energy in a sound wave of maximum pressure P dynes/cm^2 is given by $W = \frac{1}{2}\cdot\frac{P^2}{\rho v^2}$ ergs/cm^3, so that the rate at which energy is flowing outwards through unit cross-section at a distance r from the centre of the source is given by

$$\frac{1}{2}\cdot\frac{P^2}{\rho v} \text{ ergs/cm}^2\text{/sec.} \quad . \quad . \quad . \quad . \quad (2)$$

This is to be expected, since, in the absence of energy absorption in the transmitting medium, the total power radiated is constant and independent of r, while the power per unit area of a spherical surface of radius r varies inversely as r^2. From equation (2) an idea of the magnitudes involved may be obtained. A pressure of 1 dyne per cm^2 corresponds to a fairly loud sound. The steady atmospheric pressure is approximately 1 million dynes per cm^2, so that a sound pressure of 1 dyne per cm^2 corresponds to a pulsation of 1 part in 1 million of the steady pressure. It is seen that the energy associated with this sound pressure is only 10^{-9} watt per cm^2, so that a very sensitive apparatus is required to detect sounds of low intensity. It is also seen that the power varies as the square of the pressure. It will be shown later that the range of pressure that the ear can perceive as sound is of the order of 10^6 to 1. Hence the corresponding power range is 10^{12} to 1. It is easier to grasp the significance of magnitudes occurring in the smaller range than in the larger, so that the authors have adopted the expression of sound intensities in terms of sound pressure rather than of sound energy. The unit chosen is the R.M.S. dyne per cm^2 at a specified distance from the sound source. So far it has been assumed that the sound generator emits waves of sinusoidal form. In practice, however, machinery almost always emits a complex sound wave. In some cases the wave-form is of very great complexity and, unlike the e.m.f. wave-forms of dynamo-electric machinery, the component frequencies are not necessarily simple multiples of a fundamental frequency. The analysis of these complex waves into their constituents is essential in the study of the factors giving rise to noise in machinery. The apparatus described later measures the frequency and pressure intensity of each component of a complex sound wave. In sound, as in other cases of wave motion, the principle of superposition holds for ordinary amplitudes; that is, the resultant instantaneous pressure at a point in a sound field is equal to the sum of the instantaneous component pressures at that point. The discussion in this section based on sinusoidal sound waves can therefore be applied to each individual component of a complex wave, and the sound emitted by a machine expressed as the pressure intensity and frequency of each component at a specified distance from the machine, certain other test conditions, which will be dealt with later, being observed.

(3) The Characteristics of the Ear.

The literature of this subject is considerable. Lord Rayleigh * investigated the lower limit of audibility for different frequencies, viz. the intensities that were "just easily audible." He found that if the limit of audibility at 50 cycles per sec. was denoted by unity, the intensity at 200 cycles was 0·13 and at 1 000 cycles 0·05. Wegel,† using more refined methods, measured both the upper and lower limits of audition. Fig. 1 is reproduced from his paper. The lower full-line curve represents the average minimum audibility for 72 normal ears. It is seen that the greatest sensitivity occurs at a frequency of 3 000 cycles per sec. and that the intensity is of the order of 0·0005 dyne (R.M.S.) per cm^2. The dotted curves on either side of the average curve give the approximate deviation from the average that may be expected among persons having normal hearing. The upper limit of audition is the intensity at which hearing merges into feeling. The upper limit is the threshold of feeling, in the same way that the lower limit is the threshold of hearing. Wegel states that near the upper limit the feeling is first a tickling sensa-

---

* See Bibliography, (14).

† *Ibid.*, (20).

tion and then becomes acutely painful as the loudness is increased. From the maximum audibility curve in Fig. 1, which was based on 48 normal ears, it is seen that the greatest intensity that can be perceived as hearing is of the order of 5 000 dynes per cm^2 and occurs at a frequency of about 700 cycles per sec. At the upper and lower frequency limits where the curves intersect, it is difficult to distinguish between hearing and feeling. The upper limit is about 20 000 cycles per sec. and the lower about 20 cycles per sec. The sensation of feeling rather than hearing which proceeds from the 32-ft. pipe of an organ, which has a fundamental frequency of about 17·4 cycles per sec., is well known.

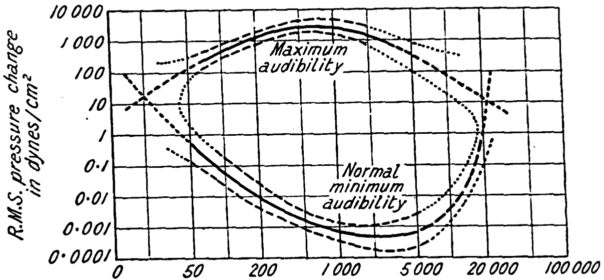

FIG. 1.—Frequency sensitivity of the ear.

So far we have considered the sensibility of the ear in regard to the limits of audibility. It is obviously difficult to construct machinery that will not emit sounds having intensities above the lower limit of audibility. The desired quantity is the value of the sound intensity which may be considered objectionable, due attention being given to the circumstances under which the sound is produced. From this standpoint the sensibility of the ear to sounds of ordinary, and not extreme, intensities and frequencies may be more pertinent. In a very able paper, Knudsen * deals with this aspect of the subject. He determines first how the sensibility of the ear to small changes in intensity varies with the loudness and pitch or frequency of the sound, and secondly how the sensibility of the ear to small changes in frequency varies with loudness and frequency. The "intensity sensibility" is expressed as the ratio of the smallest perceptible change in the energy of a note to the total energy of the note. As the authors prefer to work in sound pressure rather than energy, they will express the intensity sensibility as $\Delta p/p$. Similarly, the frequency sensibility is expressed as $\Delta f/f$. The experimental determination of these quantities, which it is unnecessary to discuss here, was carried out with great skill and refinement. The way in which the intensity sensibility varies with pressure is shown in Fig. 2. At a frequency of 100 cycles per sec. the intensity sensibility is seen to be relatively small for low intensities but increases rapidly when the intensity is increased to 1 dyne per cm^2. Above this value it becomes constant. Similarly, at 200 cycles per sec. the sensibility becomes constant for intensities above about 0·25 dyne per cm^2, and at 1 000 cycles per sec. above about 0·06 dyne per cm^2. The important point to notice is that the curves for all three frequencies converge to nearly the same value. For intensities above about 0·25 dyne per cm^2 the sensibility is very nearly independent of intensity and frequency over a frequency range of 100 to 1 000. Fig. 3 shows the intensity sensibility as a function of frequency. The curve was taken on a basis of a constant "loudness" of 100 times the threshold value. Taking Wegel's threshold values, this would correspond to pressures (R.M.S. dynes per cm^2) of about 5 at 100 cycles, 0·8 at 200 cycles, 0·2 at 500 cycles, 0·08 at 1 000 cycles and 0·06 at 2 000 cycles per sec., which are within the practically important range. It is seen that on this basis the average sensibility (of 19 ears in this case) is almost constant at the value 0·05 over the whole frequency range of 100 to 3 200 cycles. The curves marked "maximum" and "minimum" show the order of variation that may be expected among persons having normal hearing. Measurements up to 12 000 cycles per sec. showed that $\Delta p/p$ increases to about 0·1 at that frequency. Fig. 4 shows how the frequency sensibility varies with frequency. The intensities employed in these tests were 100 times the threshold intensities. It is seen that, while the ear can only detect a change in pitch or frequency of 1 per cent at 100 cycles, it can detect a change of $\frac{1}{3}$ of 1 per cent at frequencies above 800. The perception of a small change in frequency is, of course, an entirely different matter from the judging of the absolute pitch or frequency. This, as we have seen, can only be performed, even by a skilled musician, to an accuracy of about 5 per cent. Knudsen has also carried out observations on the effect of quality on the intensity sensibility of the ear, i.e. on the effect of adding harmonics to the fundamental on the value of $\Delta p/p$.

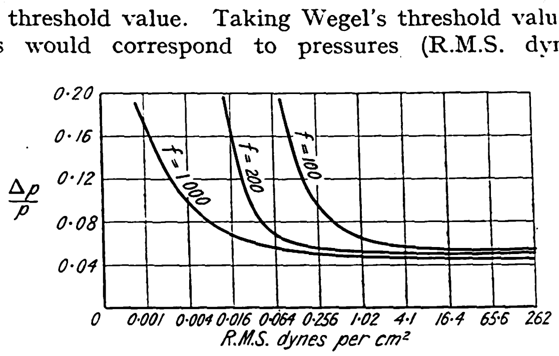

FIG. 2.—Intensity sensibility.

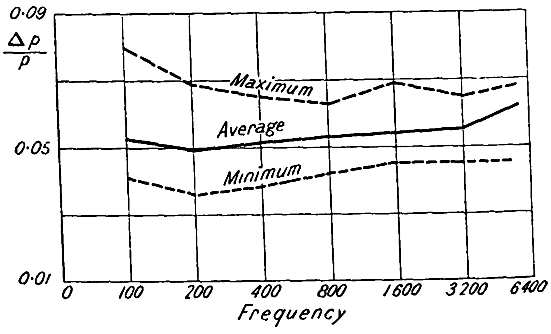

FIG. 3.—Intensity sensibility. Variation with frequency for constant "loudness."

---

* See Bibliography, (17).

He concluded that the intensity sensibility is almost independent of quality. More recent work by R. R. Riesz[*] yields results in general agreement with those of Knudsen.

It may be noted here that it is the generally accepted view that in a steady complex sound wave the response by the ear is independent of the phase relation between the component frequencies. That this is very probably true can be seen when it is remembered that the degree of constancy of the component frequencies in a complex sound wave is seldom, if ever, such as to preserve a fixed phase relationship between them. In view of this unimportance of phase the apparatus and experimental procedure necessary in analysing a complex sound wave are very much simplified.

A discussion of the characteristics of the ear is useful in considering the qualities that have to be possessed by an apparatus suitable for general sound measurements on machinery, and it will be well to consider this matter briefly before discussing particular types of measuring apparatus.

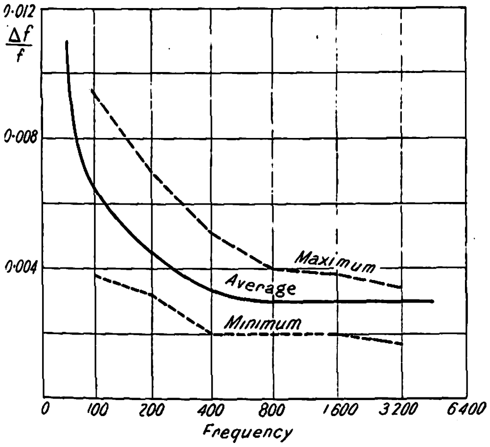

FIG. 4.—Frequency sensibility.

With regard to sound pressures, measurements have to be made on certain apparatus, such as integrating meters and transformers for domestic use, at pressures not very greatly in excess of the threshold values. On other apparatus, such as motors and heavy machinery, values of 1 000 or 10 000 times the threshold values may be reached. The measuring apparatus must therefore be sufficiently sensitive to detect the smallest intensities and yet have sufficient range of adjustment to be able to deal with the largest intensities. As regards the accuracy desirable in pressure observations, the relative accuracy of the measurements for ordinary intensities need not exceed 5 per cent and the absolute accuracy, say, 20 per cent, seeing that under favourable conditions the ear cannot detect a smaller pressure change than 5 per cent. With regard to frequency, the most generally important range is from 100 to 2 000 cycles per sec., and it is desirable to be able to take observations at any frequency from 25 to 5 000 cycles. Since the main object in measuring frequencies is to identify the source of each component of a complex wave, an accuracy of 1 per cent in the frequency observations is an advantage as it enables a distinction to be made between two components which do not differ greatly in frequency.

Table 1 may be of assistance in forming a conception of the relation between pitch, frequency and wavelength.

TABLE 1.

Source of sound	Fundamental tones	
	Frequency	Wavelength *
	cycles per sec.	cm
Highest pitch on pianoforte ..	3 520	9·7
"Middle" C of pianoforte ..	256	133
Lowest pitch of pianoforte ..	26·8	1 270
2-ft. pipe of organ	278	122
8-ft. pipe of organ	69·5	490
32-ft. pipe of organ	17·4	1 950
Note from 50-cycle electrical apparatus	100	340

* Velocity = 34 050 cm per sec.

(4) AVAILABLE SOUND-MEASURING APPARATUS.

We have seen from the previous Section that for engineering purposes we require an apparatus that will measure sound pressures in absolute units over a range of at least 100 to 2 000 cycles per sec. and deal with sound intensities ranging from very feeble to very loud sounds. In addition, the apparatus must be capable of reasonably rapid operation and also of measuring transient as well as steady sounds. In this connection it may be pointed out that, in dealing with transient sounds, some sort of graphical record, such as an oscillogram, is necessary. The sound-measuring apparatus, when of an electrical type, must therefore be capable of actuating an oscillograph when required. For steady sounds, however, oscillograms should be avoided owing to the complexity of the sound waveforms usually obtained from machinery. The analysis of these wave-forms into their components by graphical methods is a very slow and laborious process, while in many cases the wave-form is so complex as to make graphical analysis impracticable. For accurate work the direct measurement of the frequency and amplitude of each component in turn is essential. The apparatus must also be capable of being used in a works, where it may have to be put down on a rough bench and where a fair amount of vibration and electrical disturbance may be present. It must also be reasonably portable and not liable to suffer damage with ordinary handling in transit. It is not proposed to discuss in detail the various types of measuring apparatus that have been evolved. There are several instruments capable of measuring the frequencies of sounds with a fair accuracy, provided the sound wave is not very complex in character. An expedient that used to be adopted some years ago for estimating the frequency of a note emitted by a machine was to get some musical member of the staff to produce a note of equal pitch on a violin and, from the note known to correspond to the observed position of the finger on the string, to obtain the frequency. Another apparatus that has been used is a metal tube of variable length fitted with an ear-piece. The tube is adjusted until the air column it contains is in resonance with the incident sound wave, the resonance point being judged by listening in the ear-piece. While these methods, which have the great advantage of simplicity, are capable of determining the frequency of a prominent note, they give no information in regard to intensity. A simple method of obtaining a rough measure of the relative intensity of sounds of the same quality is to couple a telephone transmitter, located near the machine to be tested, to a telephone receiver placed in a fairly soundproof enclosure. The sound of the machine will be heard in the receiver and, by shunting the latter with a resistance box, the resistance required to make the sound in the receiver just inaudible can be observed. If, now, the intensity of the sound is changed, a new value of resistance for inaudibility is found. A rough measure of the relative intensities in the two cases can then be obtained from the plug-box resistance and the impedance of the receiver. The reference point used in these measurements is, of course, the threshold intensity for the observer's ear. The results are only relative so long as the sound is constant in quality, which makes the utility of the method very limited.

---

[*] See Bibliography, (19).

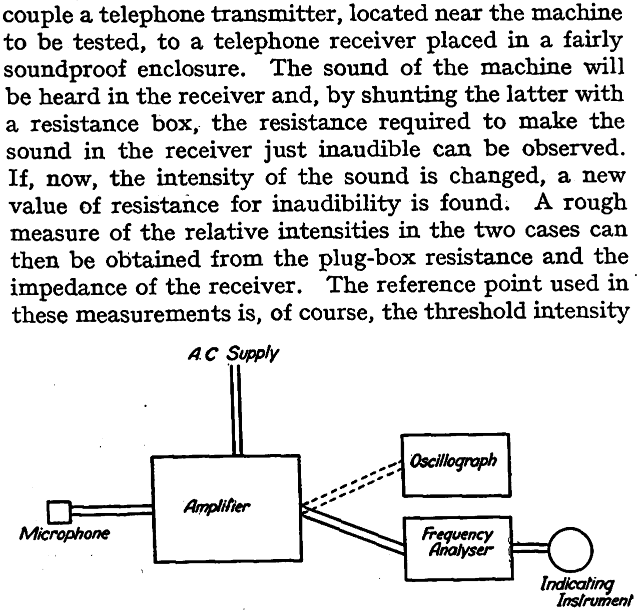

FIG. 5.

Turning now to the more ambitious methods, it is found that, broadly speaking, the methods which yield sound intensities in absolute measure are suitable only for laboratory use on account of the delicate apparatus required. Examples of absolute methods are the Rayleigh disc and the radiation pressure method. While these methods are not directly applicable to measurements on engineering apparatus, they are of great importance as absolute laboratory standards and will be discussed later in connection with the calibration of testing apparatus. Many instruments have been devised with the object of providing a simple and portable means of measuring sound. For quantitative work these instruments unfortunately suffer from one or more serious limitations. Some of them give indications in the form of a trace of the sound wave on a photographic film, which, as we have seen, is difficult to utilize for quantitative purposes. Others, especially those of the non-electrical type, employ horns and sharply resonant diaphragms, which cause the indications for a given sound intensity to vary widely and in a complicated manner with frequency. This characteristic, when embodied in an instrument which gives graphical indications, naturally causes an excessively distorted picture of the sound wave to be obtained. Another difficulty with the non-electrical types of apparatus is that the whole apparatus has to be placed in the sound field and the dimensions of the apparatus may be such as to cause serious distortion of the sound field even at comparatively low frequencies.

Electrical methods have much greater possibilities than purely mechanical methods so far as the completeness and precision of the results obtainable are concerned, and the large range of frequency and intensity that can be covered. These considerations have led the authors to concentrate on electrical methods and to develop the apparatus described in the next Section.

(5) AN ELECTRICAL SOUND ANALYSER.

(*a*) *General Principle.*—The apparatus consists essentially of a microphone which generates an e.m.f. having a known relation to the incident sound pressure, an amplifier of known characteristics, which amplifies the microphone e.m.f., and some means of measuring the complex electrical wave-form of the amplifier output. This is illustrated schematically in Fig. 5. One method of dealing with the amplified voltage of the microphone is to take an oscillogram of it. The microphone-amplifier-oscillograph combination has been used by several investigators for obtaining the frequencies of prominent components of sound wave-forms, but its use for the quantitative measurement of intensities has received very little attention. As previously pointed out, the difficulty of analysing graphically an oscillogram of a complex wave is a serious disadvantage of the use of an oscillograph, so that while we have made the method available its use is confined to transient sounds or to cases where a picture of the sound wave is desirable. It may be pointed out that in order to obtain a true record of the sound wave the instantaneous output voltage from the amplifier must at every instant be proportional to the instantaneous sound pressure. To secure this, the R.M.S. e.m.f. generated by the microphone per unit R.M.S. sound pressure must be independent of frequency and pressure, a characteristic very difficult to obtain in practice. In addition, the amplification factor of the amplifier must be independent of frequency and applied e.m.f. over the material range. This latter condition can be obtained without great difficulty. The other method of dealing with the amplifier output is to measure the frequency and amplitude of each of the components in turn by means

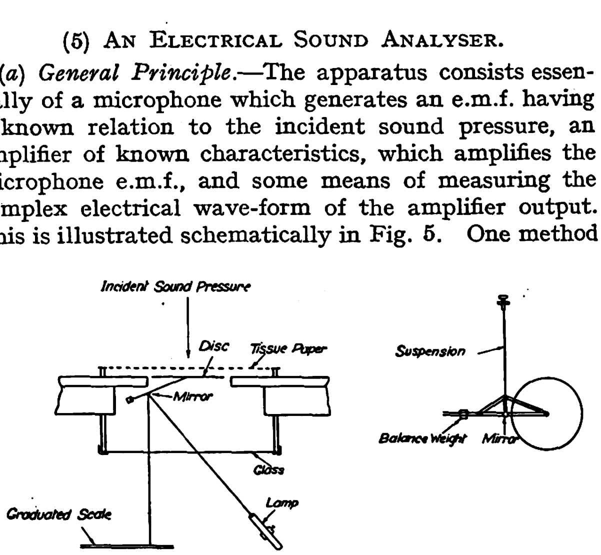

FIG. 6.—Apparatus for radiation pressure measurements.

of an electrical frequency analyser. By making the required measurements directly, this method eliminates the analysis of complex oscillograms and so obtains the values of frequency and amplitude with far greater accuracy than can be obtained by inspection of a non-periodic curve to which the ordinary rules of analysis do not apply.

Two sets of apparatus have been constructed. The original or No. 1 apparatus was largely experimental and was built before some of the many conditions which it is necessary to fulfil were fully appreciated. It will, therefore, be described very briefly. The No. 2 improved apparatus is described in detail in Section (7).

(*b*) *Considerations of the Microphone Characteristic.*—The first type of microphone contemplated for this work was the moving-coil cone type with permanent-magnet field. The great attraction of this type of microphone for quantitative work is the possibility of obtaining an instrument of permanent and calculable sensitivity and so avoiding the difficult problem of absolute calibration. Consider such a microphone under the action of an alternating air pressure.

Let m_t = total mass in grammes of the moving coil and cone;
a = effective area of the cone;
F = damping resistance in dynes per cm per sec.;
P = maximum value of the alternating air pressure;
v_d = maximum value of the alternating velocity of the cone;
x = displacement of the cone from its mean position of rest;
β = restoring force per cm deflection due to the cone support.

Then $$\frac{m_t d^2x}{dt^2} + \frac{Fdx}{dt} + \beta x = Pa\cos\omega t$$

from which $$\frac{dx}{dt} = \frac{Pa\sin\omega t}{jF + \left\{\omega m_t - (\beta/\omega)\right\}}$$

When the natural frequency of the suspended cone and coil is very low, say less than 15 per sec., the transient term is of no importance and ωm_t is large compared with β/ω over the working frequency range. If the friction term F is small compared with ωm_t we can write for the maximum velocity of the system

$$v_{m_t} = \frac{Pa}{\omega m_t} \text{ cm per sec.}$$

If, however, the damping force F is made to preponderate over $\left\{\omega m_t - (\beta/\omega)\right\}$ we have

$$v_F = \frac{Pa}{F}$$

Let the voltage generated by the moving coil per unit velocity be denoted by K_2 volts per cm per sec.

Then $K_2 = NBr \times 2\pi \times 10^{-8}$ volts per cm per sec.

where N = number of turns on moving coil,
r = radius of moving coil, and
B = average flux density in the air-gap.

The maximum voltage generated by the mass-controlled microphone is therefore given by

$$E_{m_t} = \frac{PaK_2}{\omega m_t} = \frac{PaNBr \times 10^{-8}}{fm_t} \text{ volts (max.)}$$

For the friction-controlled system the corresponding voltage is

$$E_F = \frac{PaK_2}{F} = \frac{PaNB \times 2\pi r \times 10^{-8}}{F}$$

Comparing these two equations for the voltage generated by the two types of microphone it is clear that the first one consists entirely of perfectly definite quantities which can be measured with considerable accuracy. In the second, however, the friction term F is very difficult to measure and cannot be pre-determined with any accuracy.

The great advantage, therefore, in making the mass effect preponderate over the other controlling forces is that it is possible to calculate the velocity of the diaphragm, and therefore the voltage generated by the moving coil, for a given incident sound pressure, knowing the constants of the system and the frequency of the incident pressure wave. There are, however, two disadvantages which have led the authors to use a microphone of a different type. Firstly, the use of a large mass to extend the useful range of the microphone to very low frequencies has the immediate effect of reducing the sensitivity at all frequencies. Secondly, the measurement of a small high-frequency sound and a large low-frequency rumble (a common combination) on the same apparatus is rendered difficult unless some form of frequency correction is interposed between the microphone and the amplifier. If an oscillographic record is being taken, the large low-frequency sounds, augmented by the high sensitivity of the microphone, give large amplitudes on the film, while the small high-frequency sounds, reduced by the low sensitivity of the microphone, give amplitudes too small to measure. Difficulty is also experienced when a frequency analyser is used, owing to limits on the maximum permissible amplification imposed by the last valve of the amplifier and the large low-frequency voltages generated by the microphone. To correct this unfortunate characteristic of the microphone the amplifier can be arranged to give an amplification proportional to frequency by using, for example, a suitably proportional mutual inductance to couple the first two valves of the amplifier. The overall sensitivity of the combined amplifier and microphone is then independent of frequency over the working range.

A complete apparatus on the above lines, consisting of a mass-controlled microphone, a 3-stage resistance-coupled amplifier with an additional frequency-correcting stage, power valves and output transformer, and a tuned-circuit frequency analyser, has been designed and made. As the apparatus was purely experimental and was built before all the operating difficulties were fully appreciated, the description is a general one. A more detailed discussion of apparatus design will be given in connection with No. 2 apparatus.

(*c*) *No.* 1 *Apparatus.*

The Microphone.—The magnet system is of the now familiar permanent-magnet pot type, having 8 magnets of cobalt steel. The gap density, as measured by a search coil of the same dimensions as the moving coil, was found to be 7 000 lines per cm^2. The diaphragm consisted of a 90° cone made from Bristol-board. The coil had 680 turns of 0·002 in. diam. enamelled copper wire with a mean diameter of 2·05 cm. The voltage constant, K_2, of the system is therefore 0·307 volt per cm per sec. The mass of the diaphragm and coil was originally 3·72 grammes and the effective area 64 cm^2, so that the sound sensitivity when mass-control operated was $0 \cdot 84/f$ volts per dyne per cm^2. The instrument was mounted in a bakelite tube 15 cm diam. and 18 cm long, covered at the back by a sheet of bakelite and loosely packed with cotton waste to prevent internal cavity resonances.

In order to make the amplification proportional to frequency the first valve was mounted in a separate copper-lined box together with its H.T. battery and anode transformer. The latter consisted of two primary coils in parallel and two secondary coils in series, the two pairs being arranged astatically to reduce trouble from stray fields. A non-inductive resistance of 80 000 ohms in series with the primary made the primary current independent of, and the secondary voltage proportional to, frequency up to a frequency of 5 000 cycles per sec. Provision was made for using four stages of resistance-coupled amplification, each in its own copper-lined compartment. Anode resistances of 200 000 ohms and grid leaks of 5 megohms were employed, so that in order to give good amplification at 25 cycles the capacity of the coupling condensers was made 0·01 μF. Two 66-volt dry batteries were accommodated in a compartment alongside the amplifier and supplied the requisite H.T. supply of 120 volts. The valves used had 6-volt filaments and voltage amplification factors of 35. Two power valves in parallel were supplied with 36 mA and 250 volts H.T. from the works' 250-volt d.c. mains, through a smoothing circuit. The combination had a voltage factor of 6 and, with a 3 000-ohm load in the anode circuit, gave 1 mA anode current per grid volt.

In designing the transformer for feeding the oscillograph or analyser, advantage was taken of the low magnetizing force required by certain nickel-iron alloys. This could be done only by filtering the a.c. component of the anode current from the mean value. A high-impedance choke in conjunction with a 10 μF condenser effected the filtering. Several secondary tappings were provided so that, whatever the load impedance, its value referred to the anode circuit would be 3 000 ohms.

A suitable 3-element oscillograph giving accurate records up to 2 000 cycles is available for connection to the output transformer. Records of transient sounds can thus be taken, with the added advantage that other quantities, such as currents or voltages, can be recorded simultaneously and the results correlated.

In considering an electrical frequency analyser, a few calculations based on the use of a single tuned circuit, consisting of an inductance and variable condenser, indicated that the selectivity of such an arrangement would not be good enough unless a large and expensive coil were used. In addition to being expensive a very low-resistance circuit has a very sharp resonance peak, necessitating great constancy in the frequencies being analysed. By using multiple-circuit analysers, the required selectivity can be obtained without the apparatus being highly sensitive to changes in frequency, a point of great importance in engineering testing. While analysers having more than two circuits have theoretical advantages, all that is desired may be obtained with two circuits. In such an analyser, resonance is indicated by adjusting both circuits so that a maximum current flows in the secondary circuit. Subject to certain limitations, which are discussed later in detail, the secondary inductance, capacity and the resonant frequency are then connected by the relation $4\pi^2 f^2 LC = 1$.

(6) METHODS OF CALIBRATION.

In order to be able to make measurements of sound intensity with the apparatus described, it is necessary that each link in the chain from sound energy to the deflection of the final galvanometer should be of known, permanent performance. The units involved in this transformation are the microphone, the amplifier and the frequency analyser or oscillograph. As regards the first, we must know the voltage generated by the microphone when acted upon by a sound of unit intensity at any frequency over the range required for tests, and we must also know that the voltage is strictly proportional to the sound intensity over the range of pressures encountered during testing. As in all measurements, the possibility of any change in the quantity under observation due to the presence of the measuring apparatus, in this case the microphone, must be considered. The amplifier must give a known current output per millivolt input when feeding a definite load at all frequencies considered, and must be free from appreciable amplitude distortion up to its rated output. In the same way the response of the frequency analyser or oscillograph must be known, particular attention being paid to the calibration of the analyser as a frequency meter. Finally, an overall calibration of the whole apparatus in galvanometer deflection per unit sound input is advisable as taking into account any mutual effects between the components.

The methods and technique of calibrating will be dealt with in three parts: (*a*) the intensity calibration, outlining the various methods tried for obtaining sounds of known intensity; (*b*) the frequency calibration, giving details of the frequency standards used and the method of checking test frequencies against the standards; and (*c*) the correction which, owing to the dimensions of the microphone, it is necessary to apply to the observed intensities.

(*a*) *Intensity Calibration from Moving-coil Microphone Constants.*—From the constants of the microphone, the voltage (millivolts) generated by an incident sound wave of unit intensity [1 dyne per cm^2 (R.M.S.)] over the frequency band where mass-control operates can be calculated from the relation

$$e = \frac{aprNB10^{-5}}{m_t f} \text{ millivolts (R.M.S.)}$$

where p = sound pressure in dynes/cm^2 (R.M.S.).

The next step is to determine the response of the amplifier and the final measuring device in terms of the input millivolts. When the amplifier is feeding an oscillograph we wish to know the deflection on the screen per millivolt applied to the input of the amplifier, but when the analyser is used the calibration has to be in terms of galvanometer deflections. In order to apply known small voltages to the amplifier the voltage-drop across a known non-inductive resistance carrying a measured current was included betwen the microphone coil and the filament circuit. It was thought advisable to leave the microphone coil in circuit as its impedance at the higher frequencies might affect the amplification of the amplifier, but actually no such effect has been noticed. The small known resistance consisted of a non-inductive plug-box, and the current flowing through it was measured by a thermo-junction and galvanometer. This current was supplied by a loose coupling to a valve oscillator adjusted by suitable condensers to oscillate at the requisite frequency. Having adjusted the amplifier supplies such as filament, H.T. and grid-bias voltages, including those of the frequency-correcting stage when one was used, the input voltage at a known frequency was gradually increased from zero by adjustment of the current and input resistance until a suitable response on either the oscillograph or analyser galvanometer was obtained. With the analyser, of course, both circuits had to be tuned to the test frequency and the coupling between them kept within the limits for linear response outlined in the next Section ("Design"). From the results obtained it was possible to draw graphs connecting the amplifier output or oscillograph deflection per millivolt input with frequency. Similarly the current (mA) in the secondary circuit of the analyser per millivolt input per unit coupling between the two circuits was deduced over the whole range and plotted against frequency. As measurements of amplification were made on the various studs of the potentiometer control in the anode circuit of the second valve in the amplifier and also with the first valve removed, a factor was deduced for each stud with two and three stages of amplification so that for any setting the sensitivity could be referred to that at the standard settings of three valves, stud 1 (3S1) and two valves, stud 10 (2S10).

At any frequency, therefore, within the tuning range of the coils the deflections of the oscillograph or the readings of the galvanometer measuring the secondary current of the analyser can be interpreted into millivolts generated by the microphone and so, assuming mass control, into sound pressure in dynes per cm^2 at the diaphragm of the microphone. The question as to whether that is always the same pressure as would exist if the measuring instrument were not there will be dealt with in a later Section.

Source of Known Strength.—The early attempts to check the microphone sensitivity were based on the calculation of the sound field set up by a moving-coil loud-speaker, similar in construction to the microphone but situated in plane baffles of various sizes. Tests were first made in a large laboratory, but it was soon obvious that the standing waves set up in the room made the results of little value. In order to prevent this distortion of the field due to wall reflections, the apparatus was moved on to the spacious flat roof of a laboratory building, the loud-speaker being mounted in a hole in one wall of a hut containing the oscillator for supplying the currents of varying frequency to the source. To reduce reflection from the floor and so approximate to the semi-infinite radiating space contemplated by Lord Rayleigh, large sheets of thick felt were placed on the floor underneath and in front of the loud-speaker. On plotting the response of the microphone with distance from the source at various frequencies, a series of wavy lines, each having a rectangular hyperbola as a mean, was obtained. These mean sensitivities calculated from the loud-speaker constants agreed fairly well with the values calculated from the microphone constants up to 600 cycles. The agreement was improved by providing rubber insulation between the loud-speaker and the wall of the hut, so probably the latter was vibrating and making the field strength higher than the calculated value. Above 600 cycles the sensitivity of the microphone deduced from the loud-speaker was from 1·5 to 4 times that predicted from the microphone constants. However, at 4 000 cycles the agreement was again very good. Numerous modifications were tried, such as enclosing the microphone in a padded tube, leaving the back off, removing the tube and fitting baffles of various sizes, but it was obvious that all that could be deduced from the measurements was a confirmation of the order of the sensitivities of the microphone and loud-speaker. However, in view of the reflection troubles encountered it was deemed advisable to design and make a smaller microphone on similar lines to the first. The constants of the No. 2 instrument are:—

Area of cone = 16·7 cm^2.
Radius of moving coil = 0·6 cm.
Gap flux density = 2 900 lines per cm^2.
Total mass of moving system = 5 grammes.
Calculated sensitivity = $46{\cdot}5/f$ mV (R.M.S.) per R.M.S. dyne per cm^2.

Radiation Pressure.—When a sound wave suffers normal reflection at a perfectly reflecting surface there is on the surface a resultant unidirectional force * of $0{\cdot}75\ p^2$ micro-dynes per cm^2, where p is the maximum pressure in the incident wave in dynes per cm^2. This suggests an absolute method, independent of frequency, of measuring the intensity of a sound wave, provided a sufficiently delicate radiometer can be made. The method adopted for a trial was to suspend an aluminium disc 6·5 cm diam. in a slightly larger hole in a large wooden partition 10 ft. by 9 ft. by 2 in. thick, erected across the laboratory and dividing it into two parts. As indicated in Fig. 6, the disc was supported on a light triangulated framework of small-diameter aluminium tube hanging from the finest phosphor-bronze suspension obtainable, and was balanced by a small brass weight. The line of the suspension was, for convenience in mounting, behind the plane of the disc and to one side of the edge of the disc to make sure that when a uniform normal pressure acted on the disc all the elements of the force would produce on the suspension a turning moment in the same sense. A small mirror attached to the framework at the point of contact with the suspension provided a delicate means of recording movements of the suspended system by a spot of light from a lamp reflected from the mirror and focused on a translucent scale. Since the order of the force to be measured with an incident sound pressure of 1 dyne per cm^2 was 25 millionths of a dyne or 40 micro-microgrammes weight, it is not surprising that trouble due to draughts was immediately experienced. The back of the disc, including the suspension aluminium framework and balance weight, was boxed in by a short length of bakelite tube with a glass lid, and all joints were made with putty, but still the system was unstable. The other side of the partition, where the walls, floor and ceiling were covered with 4 in. of cotton waste to prevent reflection, was covered in by a draught screen of thin tissue paper, but comparatively large circulating currents of air, probably of thermal origin, within the enclosure persisted. Owing to iron impurities the magnetic properties of the aluminium reacted with the earth's field to provide another control which did not disappear when a mica disc and glass framework were used. The method was therefore abandoned.

---

* See Bibliography, (5).

The Rayleigh Disc.—Mallet and Dutton* used a Rayleigh disc in their experiments, in a lined testing cabinet, on telephone receivers. They calibrated the disc directly by steady air currents and found the torque to be proportional to the square of the air velocity as predicted by König's formula† for thin discs

$$\mathbf{T} = \frac{4}{3}\rho r^3 V^2 \sin 2\theta$$

where $\mathbf{T}$ = torque in dyne-cm,
ρ = density of air,
V = velocity of air maximum,
r = radius of disc,
θ = angle which normal to disc makes with stream-lines of air-flow.

Later, Barnes and West ‡ went a step further and confirmed in a thorough manner the constants of König's formula. They measured the sensitivities of several discs by a mechanical apparatus producing known low-frequency alternating air currents and got very good agreement between these measured values and those calculated by the formula from the constants of the discs and suspensions.

It is clear, therefore, from these researches that the Rayleigh disc does measure particle velocities as deduced by König's formula, provided that:—

(1) The disc is thin compared with the diameter. If x be the ratio of thickness to diameter of the disc and $\mathbf{T}_0$ the torque for an infinitely thin disc, König deduces that $\mathbf{T} = \mathbf{T}_0(1 - 0{\cdot}3x)$.
For $x = 0{\cdot}01$, therefore, the correction is negligible.

(2) The diameter of the disc is small compared with the wavelength of the note under test. Barnes and West give a ratio of 1 to 5 as giving results accurate to 2 per cent in velocity measurements.

(3) The disc diameter is small compared with the diameter of any enclosing tube. A value of $\frac{1}{3}$ is quoted in the above paper as giving results accurate to 3 per cent.

For an alternating current of air $V \sin \omega t$, the torque is

$$\mathbf{T} = \frac{4}{3}\rho r^3 \sin 2\theta V^2 \sin^2 \omega t$$

$$= \frac{4}{3}\rho r^3 \sin 2\theta \frac{V^2}{2} (1 - \cos 2\omega t)$$

That is, it consists of a steady component proportional to the mean square velocity and an alternating component of double frequency. The latter has a negligible effect because the natural frequency of a thin disc supported by a fine suspension is so low and the air damping relatively high. Considering only the steady deflection, therefore,

$$\mathbf{T} = \frac{2}{3}\rho r^3 V^2 \sin 2\theta \text{ dyne-cm}$$

If the length of the suspension is l cm and the control per cm equal to $\mathbf{T}_\mathbf{R}$ dyne-cm per radian, then the twist of the disc is given by

$$\delta\theta = \frac{2}{3}\rho r^3 V^2 \frac{l}{\mathbf{T}_\mathbf{R}} \sin 2(\theta + \delta\theta)$$

If the initial inclination, θ, of the disc is $\frac{1}{4}\pi$ we have

$$V^2 = \frac{3\mathbf{T}_\mathbf{R}\delta\theta}{2\rho r^3 l \cos 2\delta\theta}$$

If a lamp is directed towards a mirror attached to the centre of the disc the reflected beam of light moves through an angle $2\delta\theta$ corresponding to a linear deflection d cm at a distance of d_1 cm from the mirror.

$$\therefore \frac{d}{d_1} = \tan 2\delta\theta$$

and
$$V^2 = \frac{3\mathbf{T}_\mathbf{R} d}{4\rho r^3 l d_1}\left(\frac{2\delta\theta}{\sin 2\delta\theta}\right)$$

For values of $\delta\theta$ not exceeding $0{\cdot}1$ radian we can write, with an error not greater than $0{\cdot}4$ per cent,

$$V = \left(\frac{3\mathbf{T}_\mathbf{R} d}{4\rho r^3 l d_1}\right)^{\frac{1}{2}} \text{ cm per sec. (max. value)}$$

Since the authors' microphone is a pressure-operated device and the Rayleigh disc measures particle velocity, it is necessary to work in a field of known distribution and with a definite relation between the pressure and velocity at two points. As experience with the radiation pressure apparatus urged the authors to adopt a sealed testing chamber, it was decided to use a closed tube containing standing waves. The relation between the maximum pressure at the ends of the tube and the maximum velocity $\frac{1}{4}$ wavelength away is given by*

$$P = \rho v \times V \text{ dynes/cm}^2 \text{ (max.)}$$

where ρ = density of medium, and
v = velocity of sound in medium.

---

* See Bibliography, (34).
† *Annalen der Physik und Chemie*, 1891, vol. 43, p. 43.
‡ See Bibliography, (36).

* See Bibliography, (7), vol. 2, p. 49 *et seq.*

Working in R.M.S. values, therefore, we have, for the pressure at the end of a tube in terms of the deflection on the scale due to the twisting of the disc supported $\frac{1}{4}$ wavelength from the end,

$$p = \rho v\left(\frac{3\mathbf{T}_{\mathbf{R}}d}{8\rho r^3 l d_1}\right)^{\frac{1}{2}} \text{dynes/cm}^2 \text{ (R.M.S.)}$$

i.e. $$p = K_1\sqrt{d} \text{ dynes/cm}^2 \text{ (R.M.S.)}$$

where $$K_1 = v\left(\frac{3}{8}\cdot\frac{\mathbf{T}_{\mathbf{R}}\rho}{r^3 l d_1}\right)^{\frac{1}{2}}$$

The conditions for the production of standing waves in the tube are satisfied if there is any whole number of half wavelengths between the fixed reflecting ends. In order, however, that the Rayleigh disc shall be at a velocity loop, the distance between it and one end must be an odd number of quarter wavelengths. The general arrangement of the apparatus is shown in Fig. 7.

The first measurements were made in a bakelite tube 137 cm long, 19·7 cm inside diameter and 21·6 cm outside diameter.

The Rayleigh disc, a disc of mica 3·8 cm diam., was suspended by a fine phosphor-bronze suspension, having a control force $\mathbf{T}_{\mathbf{R}} = 0{\cdot}66$ dyne-cm per radian per cm, from a torsion head let into the tube 35·5 cm from one end. The free length of the suspension was 8 cm and a torsion pendulum experiment gave the control of the actual suspension used as 0·083 dyne-cm per radian. Two discs of hard wood 4 cm thick were made to fit in the tube with just sufficient clearance to allow them to be moved about. A hole 2·5 cm diam. in the middle of one of the wooden discs allowed the mouth of a diaphragm type loud-speaker element to be inserted with a rubber insulating bush. The other wooden disc had a hole 7 cm diameter cut in it to take the small No. 2 microphone. Various methods were tried in order to get a beam of light axially along the tube to be reflected by a small mirror on the Rayleigh disc through a window in the wall of the tube on to a scale. The first method was to provide another little window alongside the microphone for a beam of light to shine up the tube, but this method had obvious limitations in the wavelengths to which it could be adapted. An improvement was therefore effected by supporting a small inclined-plane mirror on the axis of the tube in front of the Rayleigh disc mirror so that the beam of light could enter and leave by the same side window as indicated in Fig. 7. The lowest frequency that can be measured in this tube corresponds to a wavelength equal to the greatest distance between the inner faces of the two wooden reflectors, because the velocity measurement is made $\frac{1}{4}$ of the tube length from the microphone. This wavelength is 126 cm and the frequency approximately 265 cycles per sec. as measured by the analyser.

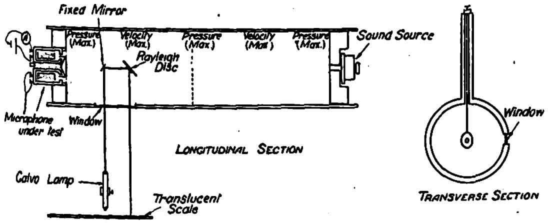

FIG. 7.—Apparatus for absolute calibration of a microphone by the Rayleigh disc.

It was found to be important to fill up all cracks and joints between the tube and wooden discs with plasticine. It was also found that unless temperature gradients over the length of the tube were prevented, a wandering zero was obtained, indicating stray air currents of the same order of velocity as those being measured. Taking the coefficient of reflection from hard wood as being unity, the corresponding factor for the microphone might be very much lower. To test for any effect due to diminished reflection from the microphone, the two wooden pistons were fixed with their inner faces at distances of 31·5 and 94·5 cm from the Rayleigh disc as indicated in the sketch, and one complete standing wave was produced in the tube. This was accomplished by feeding the loud-speaker element from a valve oscillator with frequencies in the neighbourhood of 265 cycles and adjusting the vernier condenser tuning the oscillator until the deflection of the Rayleigh disc was a maximum. A hard-wood plane disc was sub-

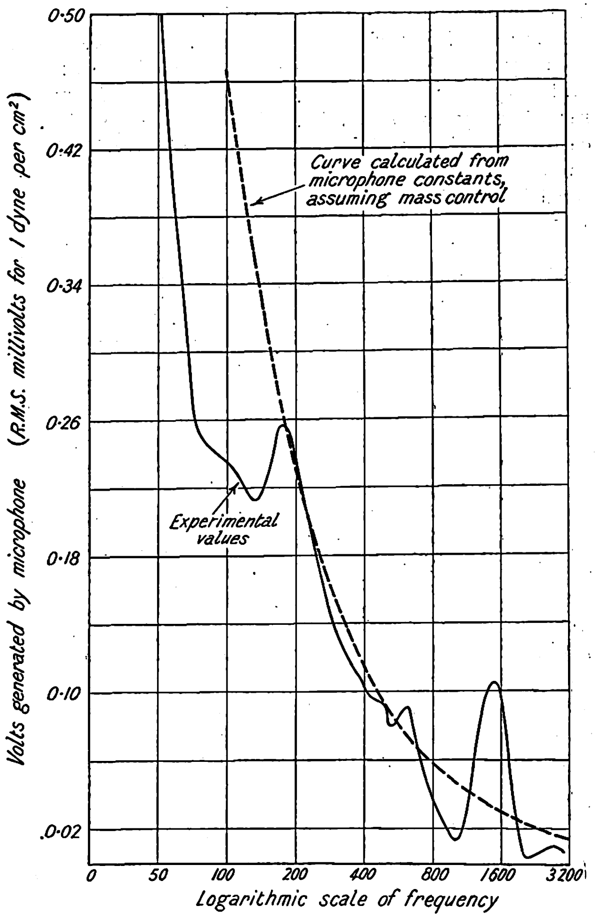

FIG. 8.—Calibration curve of No. 2 microphone.

stituted for the microphone, and the same voltage, as measured by a valve voltmeter, was applied to the loud-speaker. The resonant frequency was the same but the deflection was more than doubled. The reduction due to the microphone may have been caused by the conical shape of the diaphragm or by leakage of air between the moving coil and the central pole-piece. The cone was therefore filled in by a flat celluloid diaphragm supported from the cone by ribs of the same material. The above test, when repeated, gave the effect of the modified microphone as causing a decrease of 18 per cent in deflection or of 9 per cent in velocity. Accordingly the plane disc across the mouth of the cone was retained in all subsequent calibrations and measurements.

The sensitivity of microphone No. 2 was determined step by step by noting the response of the amplifier and frequency analyser with a sound wave of amplitude recorded by the deflection of the Rayleigh disc. By calibrating the amplifier and analyser immediately after each test at the frequency employed in the test the sensitivity of the microphone in millivolts per dyne per cm^2 was deduced.

During this calibration, which naturally necessitated taking very many readings, several important points were investigated. In the first place, measurements were made with the microphone in the centre of the wooden piston, and then the measurements were repeated with a new piston having the microphone as near to one side as possible. The readings were the same within the limits of experimental error, viz. 2 per cent.

The next point was to find out whether the results obtained with $\frac{1}{2}$ wavelength between the pistons agreed with those found with one complete wave in the tube. This was found to be the case and, moreover, the results obtained were still the same with a greater number of half wavelengths in the tube. The greatest number of half wavelengths ever used in this tube was 23, when a frequency of 1 710 cycles was tuned by a tube length of 202 cm with the Rayleigh disc at the centre. The wavelength then was of the same order as the diameter of the tube, but the results agree very well with check results made later. This discovery considerably shortened the work involved in calibrating a microphone, as it is possible to set the tube length for a low frequency, make a measurement of sensitivity, and then, with the same tube setting, make measurements on the 3rd, 5th, 7th, etc., harmonics of the gravest mode of oscillation. It is clear that the even harmonics cannot be used, as the Rayleigh disc, to be at a velocity loop, must always be an odd number of quarter-wavelengths from the reflecting pistons.

The fact that the tube responds to harmonics called for an investigation into the possibility of errors due to the presence of harmonics in the exciting unit. The analyser is very selective and its indication is unaffected by harmonics many times as large as the fundamental note. It has been shown that the Rayleigh disc does not respond to even harmonics but that it is deflected by odd harmonics. Attempts were therefore made to measure the odd harmonics of several typical notes by tuning the frequency analyser to each odd harmonic in turn. In all cases the harmonics were too small to measure, although some third harmonics could be heard faintly in a pair of telephones included in the analyser secondary circuit. This freedom from harmonics was probably due to the loosely-coupled circuit taking power from the valve oscillator to the loud-speaker element.

It was thought that if the tube diameter were of the same order as the wavelength there would be a possibility that the pressures and velocities at all points in any cross-section of the tube might not be consistent. Accordingly another testing tube was made, 76 cm long, 9·5 cm inside and 11·4 cm outside diam. Since it was impossible to accommodate a sufficiently delicate suspension inside the tube, a suspension tube having a small central hole and a torsion head at the top was made to house the phosphor-bronze strip. The hole leading into the calibrating tube is 1·5 mm diameter but, as no excess pressure ever exists there, leakage into the suspension tube does not tend to take place.

A disc 2·55 cm diam. was made by sticking together two thin sheets of paper with varnish and fastening to a suspension 31·3 cm long. A torsion pendulum experiment gave the control as 0·0208 dyne per cm per radian. With the scale 1 m from the disc the pressure is given by $p = 7\cdot 22\sqrt{d}$ dynes/cm^2 (R.M.S.), where d = deflection in cm.

As the disc was set one-quarter of the tube length from one end, the lowest frequency that can be tested in this tube is 500 cycles, corresponding to a wavelength, and distance between microphone and loud-speaker pistons, of 67·2 cm. The microphone sensitivity was measured between 500 and 1 000 cycles in the two tubes and very good agreement was obtained except at 600 cycles, when the small tube gave a result 25 per cent greater than the large tube. The difference between these two readings at 600 cycles was traced to resonance of the larger Rayleigh disc, and it is interesting to note that Barnes and West traced a 25 per cent difference to the same cause. To enable the authors to check their measurements in the large tube and also to decrease the possibility of errors due to resonance of the Rayleigh disc, a new suspension system incorporating a 1 in. diameter mica disc was made on the same lines as that for the small tube. The two measuring systems, one with a 2-in. disc and short suspension and the other with a 1-in. disc and long suspension, were arranged to fit the same hole in the top of the large calibrating tube so as to be easily interchangeable and of approximately the same sensitivity. As a result of comparative tests the 1-in. disc is used at all frequencies above 500 cycles, while the 2-in. disc, which is a little more sensitive, is used at all lower frequencies.

By adding extra sections to the large tube a length between pistons of 680 cm has been obtained with the Rayleigh disc at the middle, and so readings have been taken down to a frequency of 25 cycles.

Fig. 8 gives the results obtained by the Rayleigh disc and also the calculated sensitivity of the No. 2 microphone, assuming mass control. The agreement is fairly good between 170 and 700 cycles, but outside this band the performance of the microphone is modified by resonances. The large discrepancy at the low frequencies is due to the predominance of friction control in that region, while the large increase in sensitivity at 1 500 cycles is due to resonance in some part of the instrument.

However, the close average agreement is a satisfactory confirmation of the general accuracy of the measurements. To check the linearity of response of the microphone, observations were made with pressures up to 30 dynes per cm^2. No departure from linearity was detected.

With regard to the question of permanence of calibration, check observations taken on this microphone after an interval of 3 months of general use showed no change of calibration greater than 2 per cent.

(*b*) *Frequency Calibration.*—The amount of power required for the various stages in the calibration of the microphone amplifier and analyser was very small, amounting at the most to a few watts, but it was essential that it should be continuously variable in frequency and amplitude while remaining prefectly stable at any setting. Sine-wave generators of ample power and frequencies up to 2 000 cycles were available, but owing to the variations in the power supplies it was not possible to obtain the degree of constancy of frequency necessary for making precision measurements on sharply resonant circuits. Accordingly, a 10-watt valve oscillator was constructed with suitable coils and variable condensers to cover the frequency range 24 to 16 000 cycles in several stages. One pair of tapped coils was used up to 2 000 cycles and another pair overlapped with the first and went up to the highest frequency required.

For setting the frequency of the oscillator a range of standard tuning-forks calibrated by the National Physical Laboratory was available and these were used in the early measurements. To set the oscillator to one of the forks the operator stood with a pair of telephones on his head near the oscillator coils when the stray field was sufficient to give an audible note without connecting the leads to a search coil. A rough setting by adjusting the coil tapping and coarse-tuning condensers was made first until beats could be heard when the correct tuning-fork was set in vibration and held with its handle pressed against one telephone ear-piece. Adjustment of the vernier condenser on the oscillator then reduced the beat frequency to zero, giving an exact match. After a little practice, more points could be filled in on the calibration curve by matching harmonics of the oscillator with the forks, and vice versa, but, owing to the rapid " die away " of the 2 000-cycle fork, frequencies above this figure were very difficult to check. Accordingly the 1 000-cycle tuning-fork was maintained in vibration by a valve and suitable iron-cored coils arranged between and outside the prongs. As the method of matching by beats was getting difficult a Western Electric cathode-ray oscillograph was fed with voltages derived from the constant-frequency source and from the variable frequency oscillator, and immediately the work of frequency setting became simple and sure. The sensitivity of the oscillograph with 300 volts applied to its anode is about 1 cm deflection for 11 volts between the deflecting plates, so that it was easy to get good deflections in both directions. In general the fluorescent screen of the oscillograph is illuminated by a blue haze, but when a simple relation exists between the two frequencies the picture settles down into a simple figure. For instance, if the two frequencies are equal the general shape of the trace is an ellipse which can, however, degenerate into either of two straight lines with suitable adjustment of the relative phasing of the two supplies. When one frequency is twice the other the figure is either a " V " or an " 8." It is much easier to work with the simple " V " figure where the spot of light retraces its steps, thereby doubling the illumination, than with the other " continuous journey " figure. When the frequency ratio is 4 : 1 a " W " is obtained, and in general if there are n " V's " the frequency ratio is $2n$: 1.

In carrying out the above method for referring the oscillator frequency to the standard a small vernier condenser tuning the oscillator was mounted beside the cathode-ray oscillograph so that one observer could preserve the required pattern stationary while the other made the measurements of high-frequency resistance, amplifier response or overall characteristic of the apparatus. In this way readings could be taken at frequencies corresponding to even multiples and even sub-multiples of 1 000 cycles. In order to fill up the gaps it was found to be sufficient to make a very stable reference oscillator of another frequency, e.g. 800 cycles. To ensure consistency both anode and grid circuits were tuned and only just sufficient reaction was used to maintain the oscillations. In addition, the fitting of a high-resistance grid leak made the frequency less dependent on the supplies to the valve. The frequency of this reference oscillator, checked by a standard tuning-fork, did not vary 1 part in 1 000 in an hour.

It was hoped that a standard 1 000-cycle valve-maintained tuning-fork made to Dr. D. W. Dye's design would have been available before the completion of the calibration of the apparatus, but unfortunately this was not possible. However, the accuracy obtained is more than sufficient for commercial testing.

(*c*) *The Effect of Microphone Dimensions on Calibration.*—If we wish to measure the sound intensity at any point in space and suspend a microphone there for that purpose, it is clearly essential that we should satisfy ourselves whether or not the pressure which we measure is that which would have existed in the absence of the microphone. If the microphone forms part of a large reflecting surface, then the pressure immediately in front of the surface is the sum of those due to the direct and reflected waves. For a good reflector, therefore, the voltage generated by the microphone is twice what it would be if the measuring instrument were of negligible size. It is obvious that the size of reflector required to produce this doubling effect must depend on the wavelength of the incident sound, since a given reflector might be large compared with the wavelength of high-frequency sounds and negligibly small compared with that of the sounds of low frequency. Microphones Nos. 3 and 4 are both about 10 cm diameter, so that one naturally expects them to have no effect on low-frequency sounds but to have a transition stage as the frequency is increased, until, at some high frequency, complete reflection takes place, resulting in an apparently doubled sensitivity.

To investigate this point a series of tests was carried out in the non-reflecting room of the acoustic laboratory, which is described in Section (9). The walls of this room are lined with cotton waste to minimize reflection effects, and a preliminary exploration of the sound field produced by a source in the centre of the room indicated that reflection had been very nearly eliminated. A point 150 cm from the sound source, a small loudspeaker unit, was chosen as being in a uniform part of the field, and the microphone, supported on its spring stand, was placed there. The stand itself is designed to offer as little obstruction as possible to the sound field. A range of baffles from 11·5 to 76 cm diameter was obtained with central holes 9·8 cm diameter to fit the microphone tightly, so that it was a simple matter to make rapid alterations in the effective dimensions of the detector. With a constant input of a definite frequency to the source the response of the microphone by itself and with each one of the baffles in turn was noted, frequent checks on the source being made by returning to the no-baffle condition.

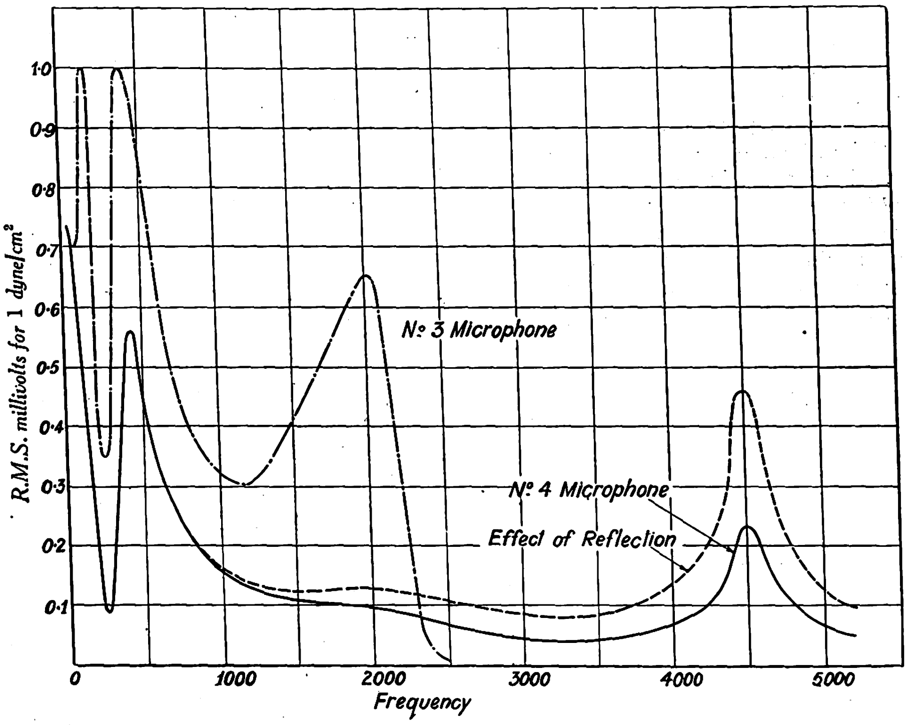

FIG. 9.—Microphone calibration curves.
Sensitivity in mV/dyne/cm² (both R.M.S. values).

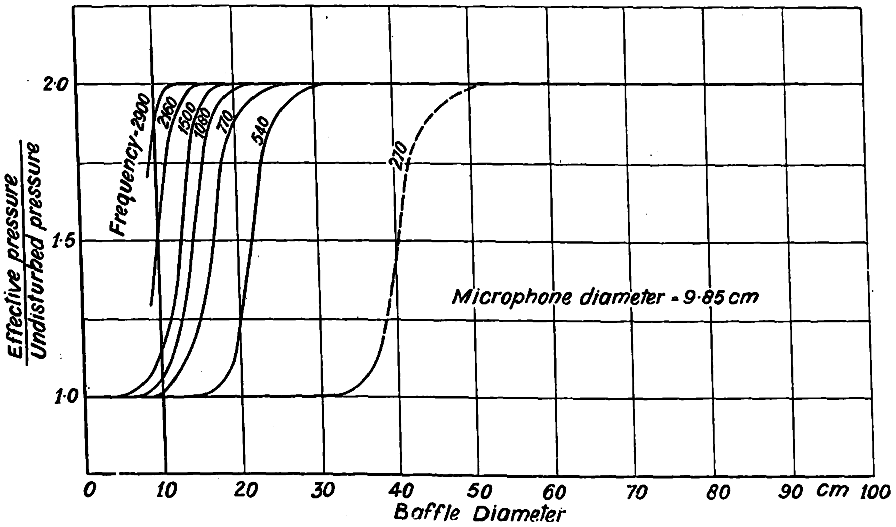

FIG. 10.—Effect of microphone dimensions.
Test carried out in non-reflecting room 587 × 587 × 293 cm high. Source at centre of room and 110 cm from floor. Microphone 150 cm from source.

The results obtained are indicated in Fig. 10. At the lower and medium frequencies the change-over from the case of the undisturbed field to that of complete reflection is clearly shown; the results have therefore all been plotted on a common arbitrary scale of 1 to 2.

At the high frequencies, however, appreciable reflection takes place from the microphone by itself. When, therefore, an increase in baffle diameter produced no corresponding increase in response it was assumed that the condition of complete reflection and doubled sensitivity had been reached. Taking this value as 2 on the scale the values for the smaller baffles and microphone alone were readily deduced.

From the points where this family of curves crosses the ordinate corresponding to the microphone diameter the correction curve given in Fig. 11 has been deduced. If, therefore, we multiply the sound pressure deduced from the Rayleigh disc calibration by the appropriate correction factor, we obtain a measure of the sound intensity which would obtain in the absence of the microphone.

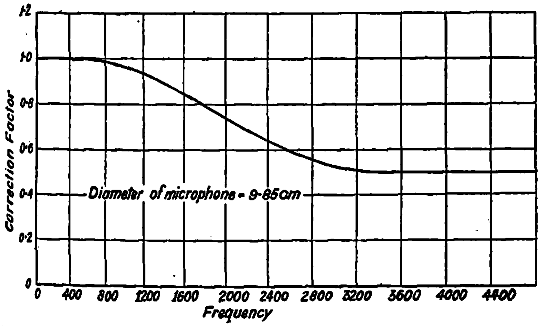

FIG. 11.—Microphone correction factor (to allow for finite dimensions).

(7) No. 2 APPARATUS.

(*a*) *Design.* — Having established an independent method of calibrating a microphone, it is no longer necessary to retain the mass-controlled type with its calculable performance, although it has been very useful in the development of the authors' technique of sound measurement. It is therefore possible to take any pressure-operated microphone with a plane reflecting diaphragm and permanent characteristics and calibrate it for use in conjunction with the rest of the measuring apparatus. However, owing to the strictly limited capacity of the amplifier power valves it is advisable to choose one having a sensitivity with frequency as uniform as possible. The questions of variation of sensitivity with sound amplitude and with everyday use must also be considered, particularly in moving-iron type instruments. The permissible impedance, having regard to the distance of the microphone from the amplifier, is very important and is bound up with the question of trouble due to stray e.m.f.'s being induced in the leads. In a works where a long lead connects the microphone on one of several testing departments to a central instrument room the maximum permissible impedance makes undesirable certain types of microphone such as the condenser type, which would have to be calibrated with the leads finally used. These considerations and others of convenience made it seem advisable to retain the moving-coil type of microphone in a modified form, giving greater average sensitivity and less variation with frequency. For other test conditions and for frequencies higher than 5 000 cycles per sec. the condenser microphone as developed by E. C. Wente * may be more suitable. Fig. 9 gives the sensitivity of No. 4 microphone with frequency, as measured by the Rayleigh disc method in the two resonant tubes. Excellent agreement between the results in the two tubes at frequencies from 500 to 1 900 cycles was obtained in this calibration except at 600 cycles, as noted previously, where the large disc was giving trouble due to resonance. Apart from these two frequencies where the difference amounts to 25 per cent, the agreement is within the limits of experimental error, viz. 2 per cent. The dotted curve gives the characteristic of an earlier microphone, which was deficient in sensitivity above 2 200 cycles.

For connecting the microphone to the amplifier, twisted leads in flexible metallic tubing are used for short distances and two twisted wires in lead covering for permanent connection from the testing departments to the central testing room. The twisting prevents inductive, and the metallic sheath capacitative, "pick-up" by the leads. To minimize stray "pick-up" on the microphone itself the magnet system is joined to the sheath of the connecting cable and earthed. The higher the impedance of the microphone the more difficult it becomes to provide an effective electrostatic screen and also the more effect the cable capacity has on the sensitivity as measured at the amplifier end of the cable. The effect of the connecting cables on all the microphones is inappreciable up to 5 000 cycles.

The amplifier, which is arranged for a.c. mains operation and for rapid calibration, is shown diagrammatically in Fig. 12. It consists of 3 resistance-capacity coupled stages employing 6-volt valves with voltage amplification factors of 30. With anode resistances of 200 000 ohms the actual amplification per stage is 20, giving a voltage amplification of approximately 8 000. The anode resistance of the second valve is arranged as a potentiometer so that the amplification can be varied down to 1/24th of the maximum value in steps of approximately $\sqrt{2}$. Each stage has a separate H.T. supply circuit to avoid resistance reaction effects. The now well-known connection of series resistance and condenser to a common source of 230 volts (d.c.) was adopted.

Two power valves are operated in parallel from the same common 230-volt d.c. source generated by a full-wave rectifier and transformer. The smoothing circuit is conventional and the anode choke is of large proportions to have an inductance of 100 H with a steady component of anode current of 36 mA.

The output transformer has a nickel-iron core to reduce the magnetizing current required at the low frequencies contemplated. The primary is fed through a large anode-feed condenser. The secondary has four windings for operating the oscillograph or the various ranges of the frequency analyser. These tappings are so proportioned relative to the load resistance which they feed that the primary impedance of the transformer is always equal to the impedance (3 000 ohms) of the power valves.

---

* See Bibliography, (41).

The power transformer for supplying the H.T. current has three primary taps so that it can be connected to 110-, 220- or 440-volt mains, and the core section is such that frequencies down to 25 cycles can be used.

The whole amplifier, including the voltage stages and power valves, is enclosed in a copper-lined section of a box the remainder of which accommodates the two transformers, chokes, condensers and a panel carrying filament and H.T. voltmeters and an anode-current milliammeter.

An auxiliary 4-volt winding on the power transformer supplies the lamp of the reflecting galvanometer of the analyser and also feeds a calibrating potentiometer which applies known voltages of the power frequency to the amplifier for rapidly checking its amplification.

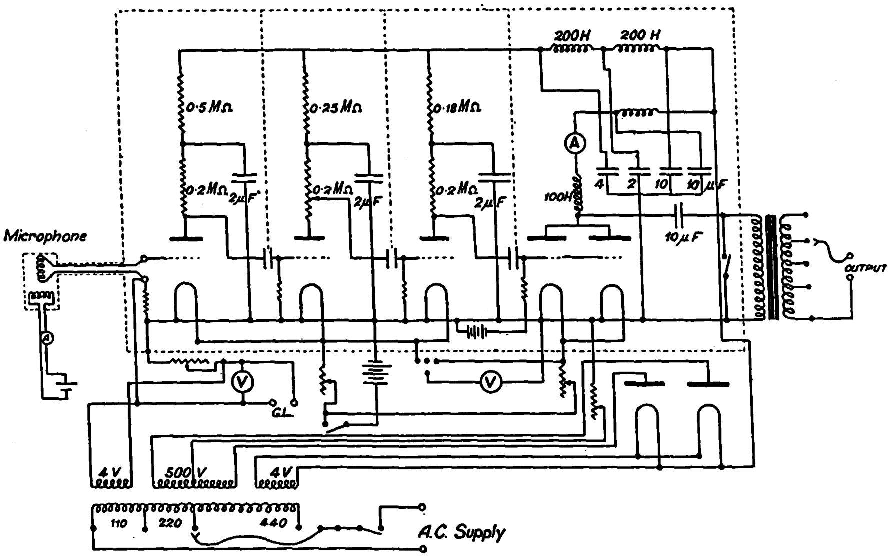

FIG. 12.—Amplifier unit.

In view of the complex sounds to be analysed, no definite selectivity requirements could be stated when designing the circuits of the analyser. Work with the first apparatus indicated that the more selectivity one had, without making the resonance curve too pointed, having regard to the variation of frequency encountered, the better. It was therefore decided to fix the width of the "flat top" of the resonance curve from considerations of possible frequency variations, and to make the selectivity comply with this limit. For this purpose the "flat top" of the resonance curve of the analyser is defined as the fractional change of frequency from the central resonant value to where the ordinate of the curve has decreased 2 per cent. If we denote this frequency change by x its value for a single tuned circuit is given by $x = R/(20\pi fL)$, where R and L are the resistance and inductance of the single circuit and f the resonant frequency. The value of x expressed in cycles is, of course, $R/(20\pi L)$.

For two similar "loosely coupled" circuits, the "flat top" of the resonance curve is given by $x' = R'/(28\pi fL')$ or, expressed in cycles, $R'/(28\pi L')$.

It follows, therefore, that for the same width of flat top the ratio of resistance to inductance is 1·4 times for two circuits what it is for a single circuit. Using these relative values of R/L it is easy to show that the frequency displacement from the central resonant value necessary to cause a reduction in circulating current to one-fifth of the maximum value is nearly twice as much for the single as for the double circuit. In other words, for the same immunity from trouble due to small frequency variations, the frequency spacing between two equal-amplitude components which can each be measured with not more than 2 per cent error in R.M.S. value due to the presence of the other is half as great for a two-circuit analyser as for one of the single-circuit type.

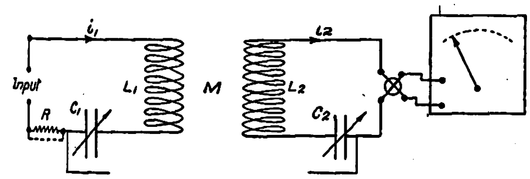
It was therefore decided to keep to the two-circuit type of analyser and so to adjust the values of R/L so that the "flat top" $x = 0\cdot2$ per cent. Since the value of x expressed in cycles is constant for a given value of R/L it is necessary to divide the frequency band to be covered into several narrow bands each with a suitable R/L value in order to prevent wide variations in the percentage selectivity. This is conveniently carried out by having several coils of suitable resistances and inductances so that in conjunction with two variable condensers the desired frequency band can be covered. A diagram of the analyser circuits is shown in Figs. 13 and 14. Four pairs of coils tuned by two 3-dial mica variable condensers of 1·11 μF capacity are used on the ranges 24–86, 86–310, 310–1 120 and 1 120–4 000 cycles. For x to be 0·2 per cent at the top of each range the corresponding values of R/L are respectively 15, 55, 200 and 700. Air-dielectric variable condensers of 0·001 μF bridge the gaps of the 3-dial condensers and make it possible to use the fourth pair of coils up to 16 000 cycles if necessary.

In operation, since both circuits are tuned to the frequency of the applied voltage, V_1, the primary current I_1 is equal to V_1/R_1, where R_1 is the total resistance of the primary circuits.

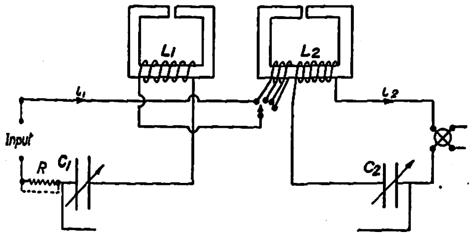
If M is the mutual inductance between the two circuits

$$I_2 = V_2/R_2 = \omega M I_1/R_2 = \frac{\omega M V}{R_1 R_2}$$

The voltage applied to the first circuit is therefore quite a simple function of the frequency, the coupling, the circuit resistances and the current flowing in the second circuit. However, as pointed out in connection with the calibration of the first apparatus, the effective resistance of circuit 1 includes a term $r_1 = (\omega M)^2/R_2$ due to the presence of circuit 2. Unless this term is negligible compared with R_1 the sensitivity of the analyser per unit coupling varies with M and makes an overall calibration difficult. If ωM does not exceed $0{\cdot}1\sqrt{(R_1 R_2)}$, then the transferred resistance is not greater than 1 per cent of the circuit resistance and can be neglected. The transferred inductance $L_1 = -(\omega M/Z)^2 L_2$ is also negligible if the above limit of coupling holds, so that the selectivity of the analyser can be estimated from the two circuits taken separately. In other words, if the given limit of coupling is not exceeded the sensitivity per unit coupling and the selectivity are independent of coupling. A rigorous mathematical investigation * of the problem upholds these conclusions. In passing, it might be added that greater values of M can be used, provided the total resistance of the primary circuit, including the transferred resistance, is determined either by measurement or by calculation and that it is understood that the selectivity for small frequency-changes is impaired. It is important, however, that the limit given by $\omega M = \sqrt{(R_1 R_2)}$ should not be passed, otherwise the tuning of one circuit will affect the other and "double humps" will appear in the resonance curves of the two circuits. The immunity from interference from a large component of widely different frequency may not be affected appreciably even when $\omega M = \sqrt{(R_1 R_2)}$, due to the large impedance of the secondary circuits at that frequency. The above point is of great assistance when using the analyser by itself for electrical wave-form analysis, a function for which it is eminently suitable. The resistance of the primary circuit, including any transferred resistance and the effective resistance of the source under test, is obtained by the added-resistance method, made convenient by the provision of a switch which inserts known non-inductive resistances in series with the rest of the circuit.



Coupled coils of equal inductance (air core for high frequencies).



Coupled coils of equal inductance (iron-nickel core for low frequencies).

FIG. 13.—Schematic diagram of electrical frequency analyser.

As regards the coils themselves, the two higher-frequency pairs are each wound on bakelite tubes in four sections to reduce self-capacity. One of each pair is made to rotate to vary the mutual inductance, which is calibrated in millihenrys. The two lower-frequency pairs of coils have cores of nickel-iron alloy to enable the requisite R/L values to be obtained in a small space and at a reasonable cost. Each core has an air-gap which alone controls the inductance of the coils, so that there is no appreciable variation of inductance with current amplitude. A small change in effective resistance with current is unavoidable and is made as small as possible by suitable proportions of core section and coil turns. The coupling between the two pairs of iron-cored coils is varied by having tappings on the secondary coils brought out to two stud switches so that a number of turns on the secondary coils can be connected in series with the primary coils.

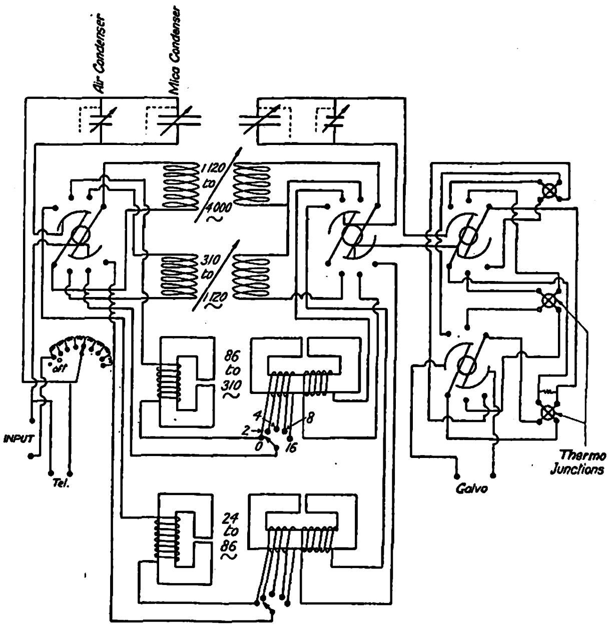


FIG. 14.—Diagram of connections of an electrical frequency analyser.

The secondary current is measured by one of three thermo-junctions and a portable reflecting galvanometer. Two double-pole coupled 3-position switches select a thermo-junction of suitable heater resistance, connect it in circuit and also connect its couple to the galvanometer.

This arrangement provides sufficient sensitivity for measuring sounds of the intensities met with in general

---

* Due to Mr. J. D. Cockcroft.

engineering work. For tests in the laboratory on apparatus which emits relatively small intensities, a 5-fold increase in sensitivity is obtained by using a laboratory-type reflecting galvanometer. For testing apparatus which emits only the feeblest sounds a further increase in sensitivity is obtained by amplifying the current circulating in the secondary circuit of the frequency analyser before applying it to the thermo-junction galvanometer. This is carried out by a 3-stage resistance-coupled amplifier of conventional design which feeds the thermo-junction through a choke-condenser-transformer system. By means of this extra amplification it is possible to measure sounds below audibility level up to 500 cycles.

(*b*) *Performance.*—The performance of the No. 2 sound apparatus follows very closely that aimed at in the design. The sensitivity of the amplifier by itself is very little affected by frequency down to 24 cycles, the maximum reduction being 14 per cent. At frequencies above 2 000 cycles there is a gradual droop in the response curve, but this is of secondary importance to the apparatus as a whole since an overall calibration is required in any case and each component frequency is measured separately. The selectivity of the analyser has been sufficient for all the various uses to which it has been put. Curves have been prepared giving the resistance of the coils over the intended range of 24 to 4 000 cycles, with an extension of range (4) to 16 000 cycles.

The frequency calibration shows that the distributed capacity of the coils is negligible over the range for which they were designed, the curves of frequency against $1/\sqrt{C}$ being straight lines except above 6 000 cycles, where the curve for range (4) begins to bend.

The expression for the sound intensity in terms of the current (I) indicated by the analyser galvanometer is

$$p = \frac{I \times m \times 10^3}{F \times K_2 \times M \times S} \text{ R.M.S. dynes/cm}^2$$

where m = microphone correction factor,

K_2 = mA/mV/mH,

M = coupling between the two analyser coils, in mH,

S = microphone sensitivity, in mV per dyne per cm^2.

The factor F is dependent on the setting of the amplifier potentiometer. Its value is obtained from a table, as it varies very little with frequency.

Ranges (1) and (2) have a common thermo-junction, while (3) and (4) have one each. In reading off the current, therefore, the curve corresponding to the range in use should be consulted. Similarly the values of mA/mV/mH should be taken from the curve corresponding to the range in use, as the ranges overlap slightly.

The curves of microphone sensitivity and correction factor could be combined into one curve, but they have been kept separate to illustrate the effect of the dimensions of the microphone.

The ease with which the sensitivity of the amplifier and measuring apparatus can be checked is very useful. By turning a switch, various small voltages from 0·4 to 12 mV of the power-circuit frequency are applied to the amplifier, and the response on the oscillograph or analyser gives an indication of the consistency of the amplifier. The values obtained when the apparatus was calibrated can be read from the appropriate curve and a correction factor deduced. By this means the readings are consistent to ± 2 per cent.

In making measurements with this apparatus it is possible to save time by making a preliminary aural estimate of the various components in the noise to be analysed. As a result of experience the operator can say, for instance, that there is no need to try ranges (1) and (4) as all the components are between 100 and 1 000 cycles—a very common state of affairs. In any case the following few notes will indicate the method of making a complete analysis of a noise. The sequence of adjustments and the starting point in the frequency range are largely a matter of personal opinion, but the method described here is the result of the authors' experience in a large number of tests.

Having set the microphone in the desired position with respect to the noisy apparatus, the amplifier is connected to suitable a.c. mains and the valve filaments to a 6-volt battery. The filament and H.T. voltages are adjusted to the correct values by means of the controls provided, and the output transformer is connected to the input terminals of the analyser. The terminals of the output transformer should be chosen to correspond to the range in use.

A pair of 120-ohm telephones is connected in series with the primary circuit of the analyser, and shunts varying from 0 to 500 ohms can be connected in parallel to vary the sensitivity and selectivity. Starting with the highest frequency range and 500 ohms across the telephones it is probable that most of the high-frequency components will be heard more or less accentuated by the tuning of the circuit. The operator concentrates his attention on the highest-frequency component present and adjusts the primary condenser until this particular component is as loud as possible. The next step is to decrease the shunt across the telephones until the note is only just audible. It will now be found that the note is much more sensitive to adjustments of the condenser. The process of tuning and reducing the shunt is continued until finally the telephones are short-circuited. The secondary condenser is then made to correspond to the primary, and the coupling between the two circuits is increased until the galvanometer deflects. It is important, however, if maximum selectivity is to be retained, not to exceed the maximum linear coupling for the particular setting of the condenser and coil. Larger values, up to two or three times, can be used when selectivity is not a limitation. The value is obtained from a graph, but can be remembered after a little practice. Final adjustments are then made to the secondary and primary condenser, and the coupling is adjusted within the permissible limits to give a good deflection on the galvanometer. If necessary the sensitivity can be varied by the amplifier potentiometer. From the reading of the secondary condenser the frequency of the component is obtained from the calibration graph, and from the coupling and galvanometer deflection the sound pressure at the microphone is deduced from the overall calibration of the apparatus. Having obtained the necessary information, attention is turned to the next lower component. It frequently happens that, instead of a pure note, a band of frequencies is encountered. In this case it is obvious that the amplitude readings will have to be referred to the particular width of resonance curve employed. The usual procedure is to take readings of amplitude and frequency right through the band and to deduce the approximate width of the band from this spectrum. It is very seldom, however, that one is able to trace such a band of frequencies to its source, as, clearly, the component frequencies do not bear a simple relation to the speed (revs. per sec.) of the motor or turbine or whatever machine is being tested. With regard to the effect of temperature on the test conditions and apparatus, such effects can be ignored if temperature variations do not exceed ± 5 deg. C.

(8) TEST-CONDITIONS FOR GENERAL SOUND MEASUREMENTS.

A little consideration will make it clear that the sound intensity measured near a source is dependent on the presence of other bodies in the sound field. These bodies give rise to local reflection or absorption and hence modify the sound field to a degree depending on their dimensions and on their acoustical properties. It is therefore necessary to devote some space to the discussion of the conditions under which sound measurements on engineering apparatus are made, and to define the conditions necessary in order that the results may be susceptible of simple interpretation.

Broadly speaking, two cases arise in practice, viz. those in which the test-conditions are under control and those in which they are not. In Section (2) of this paper the ideal condition of infinite space, in which no other body than the sound source is present, is assumed. The nearest approximation to this condition is a large, open piece of ground free from buildings, trees or other objects which would cause reflection. Even so, there will be reflection from the ground. This may be minimized by working at a sufficient height above the ground. Many workers have experimented under these conditions. In the early stages of this investigation, a small part of the work was carried out in open space, the flat roof of a laboratory building being used. While a fairly satisfactory freedom from reflection was obtained, the disadvantages of rain, wind (which had a curious effect on the sound distribution) and extraneous noises were prohibitive. It was therefore necessary that efforts should be directed to obtaining satisfactory test-conditions in a building. The obvious difficulty of carrying out sound measurements in a building where other activities are going on, such as a factory building or even a laboratory building, is that of extraneous noise. It is clear that, if useful results are to be obtained, the intensity of extraneous noise must be small compared with the intensity of the sound under observation. In the measurement of feeble sounds this condition is the most exacting of those which have to be fulfilled. It was therefore decided to construct a special building for acoustical work, so that the greater part of the projected investigation of the subject could be carried out under sufficiently defined conditions. The building, which is described in detail later, performs three main functions, viz. the reduction of extraneous noise to a tolerable value, the provision of a testing space reasonably free from reflection and the provision of accommodation for the fundamental standards of sound measurement. Extraneous noise from inside the building is minimized by placing the apparatus under test and the detector element of the measuring apparatus in a soundproof room in the building, all other apparatus being excluded. The measuring and auxiliary apparatus, together with the observer, are located in adjacent rooms. Extraneous noises from outside the building are dealt with partly by the location of the building in relation to sources of extraneous noise and partly by adopting a suitable construction. The objection to reflection in a room in which sound measurements are being made arises in the following way. Suppose that the sound source under test is located in infinite space free from obstacles. Then, from Section (2) and equation (1), the sound pressure varies inversely as the distance from the source, and one observation at a known distance is sufficient to enable the intensity of a sound of a given frequency to be determined.

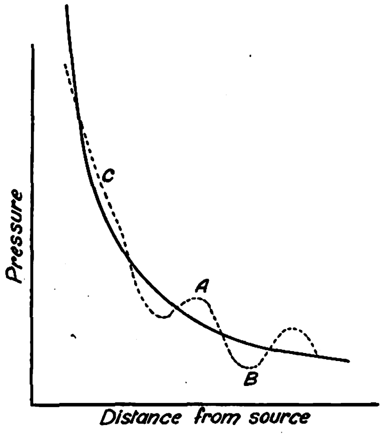

FIG. 15.

If reflection is not reduced to a negligible amount, the incident and reflected waves, travelling with equal and opposite velocities, produce an interference pattern. This gives rise to a pressure/distance relation such as that shown by the dotted line in Fig. 15, the full line showing the normal relation. When the interference effect is large, its presence may be detected by walking or moving the head slowly towards or away from the source, when points of maximum and minimum intensity will be noticed. Hence if reflection is present but unsuspected, observations with the detector at points such as A or B will be considerably in error. It is possible, of course, when reflection is suspected, to trace out a curve such as CAB and draw a mean curve through it, thus largely eliminating the effects of reflection. When, however, a machine is being tested which may emit half a dozen or more frequencies, and a pressure/distance curve has to be plotted instead of taking a single observation for each frequency, the advantage of making reflection effects negligible is obvious. Therefore, where it is practicable, measurements should be made in an enclosure designed for the purpose.

We have now to consider the case where, owing to circumstances not under control, measurements have to be made in a factory building, power station, substation or elsewhere. This usually occurs on account of the size of the machine to be tested. Although the walls of such buildings are highly reflecting, the interference trouble may not be prohibitive if the building is large and the machine is not close to a wall or switchboard or to another large machine. Where reflection is suspected, a pressure/distance curve should be taken. Extraneous noise, sometimes very loud, confused and variable, is the main difficulty. From the experimenter's point of view large machines fortunately make a large noise compared with small ones, so that the notes under observation may stand out clearly against the general background of noise. On the other hand, the detector must be placed at a distance not small compared with the dimensions of the machine, otherwise an exaggerated impression of the importance of certain components may be obtained. The necessity of placing the detector at an increased distance compared with that suitable for small machines somewhat discounts the contrast that would otherwise be obtained. It is here that the principle of dealing with each component of a complex sound in turn, rather than obtaining a simultaneous record of the whole sound, is particularly valuable. The relevant notes can often be quickly identified. If the machine under test can be shut down for a short time and the extraneous noise remains reasonably constant, the supposed irrelevance of certain notes can be checked. With small machines it may be remarked that attempts to make sound measurements on, say, a normal 10-h.p. motor on a factory test-bed, where several other machines are running and where the background of noise is large, are quite futile. It is not that the results may be inaccurate; they will probably be unintelligible.

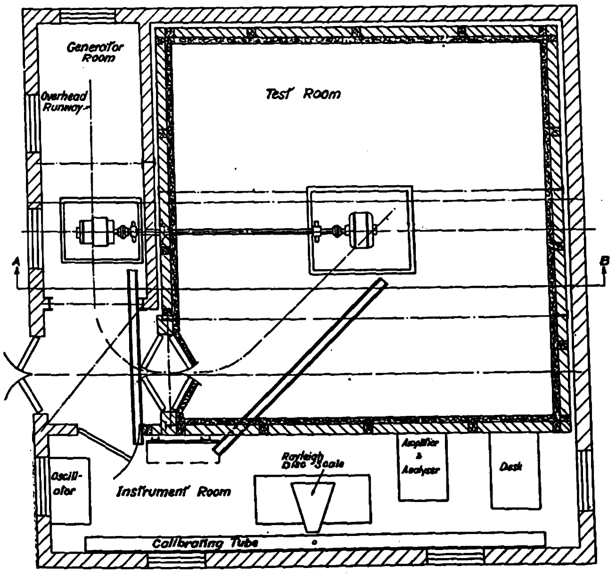

FIG. 16.

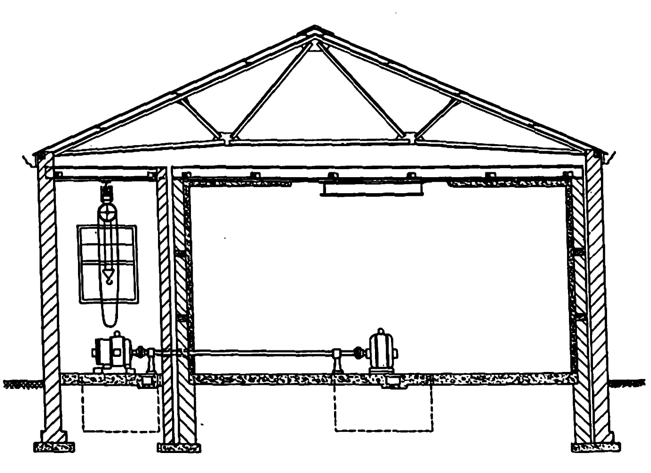

FIG. 17.

The authors' experience in testing machines of various kinds has shown that several other factors besides reflection and extraneous noise may have an important influence on the results obtained. For example, temporary test foundations may modify the magnitude and distribution of the sound considerably. Auxiliary test equipment, such as driving motors and loading brakes, may contribute no inconsiderable part of the total sound observed and must not be overlooked. Want of dynamic balance and want of alinement in a temporary set-up are also important factors. It is also necessary to guard against the direct transmission of vibration from the machine under test to the microphone, and electromagnetic or electrostatic "pick-up" from power circuits adjacent to the sound-measuring circuits. In this connection the electromagnet type of moving-coil microphone, compared with the permanent-magnet type, has the great advantage that the magnetic field may be temporarily switched off, thus facilitating the detection of "pick-up."

(9) LABORATORY FOR ACOUSTICAL WORK.

The laboratory, a plan and elevation of which are shown in Figs. 16 and 17, is a double-walled brick building resting on substantial concrete foundations. It consists of three rooms: the test room with non-reflecting walls, the instrument room in which is located the sound-measuring apparatus, and the generator room, which provides acoustical isolation for the generator used for a load in connection with the testing of motors.

The test room, which is formed by the inner shell of the building, is 20 ft. long, 20 ft. wide and 10 ft. high. Thus, when apparatus is placed in the centre of the floor for test, there is a minimum distance of 10 ft. to the walls and ceiling. The walls, floor and ceiling were first covered with a layer, 10 cm thick, of specially purified loosely packed cotton waste held in position by wire netting of coarse mesh. The cotton waste on the walls is prevented from slipping down by thin narrow shelves placed at intervals in the height of the walls. The walls of this room are of hollow brick 6 in. thick and are completely separated from the 9-in. solid brick outer wall by a 3-in. air space. The only point of connection between inner and outer walls is at the foundations, which are well below ground-level. Incorporated in the inner walls are steel stanchions, which carry girders for supporting a runway for a 1-ton block and tackle. The runway is arranged to pass over the centre of the test room, so that a motor or other apparatus to be tested can be lowered on to a bedplate to which it can be bolted during a test. The bedplate consists of a massive concrete block, the top of which is covered with a thick steel plate provided with suitable clamping arrangements. The block is let into the ground so that the top is level with the floor of the room. The sides of the pit containing the block are separated from the block by a 2-in. space to minimize the transmission of vibration from the block to the floor of the room.

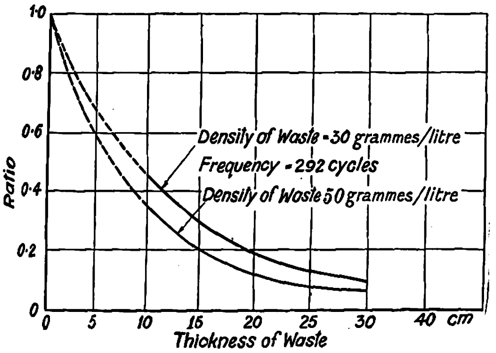

Fig. 18.—Curve of ratio (mean velocity with waste/mean velocity no waste).

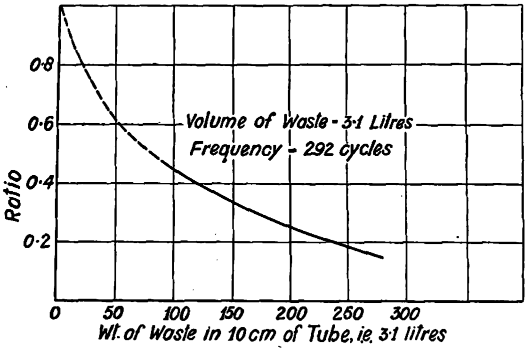

Fig. 19.—Curve of ratio (mean velocity with waste/mean velocity no waste).

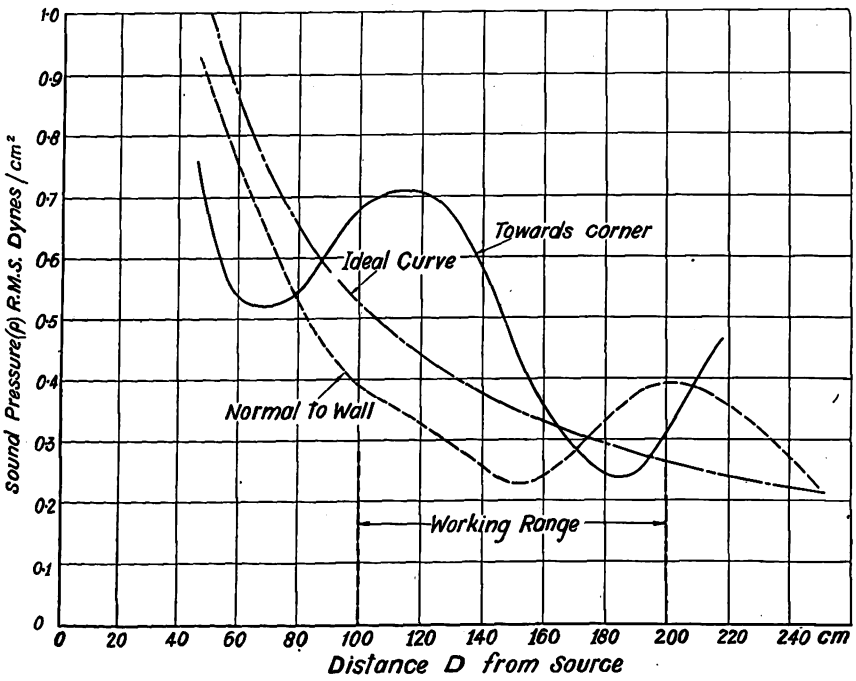

Fig. 20.—Pressure distribution curves in lined test room.

Frequency = 170 cycles per sec. Source at centre of room and 15 in. above floor-level.

The floor of the room is of concrete and the ceiling of wood. Double doors are provided, the inner sides of the inner doors being covered with cotton waste. The runway passes through those doors to a point opposite the main door of the building. It then curves round into the generator room. By this means, lifting facilities are available for handling apparatus coming in for test, and also for easily moving any apparatus in the generator room. To avoid the transmission of sound or vibration into the test room through the runway, a short gap is left in the latter near the test-room door. The test room is ventilated by suitable ducts and a fan which is

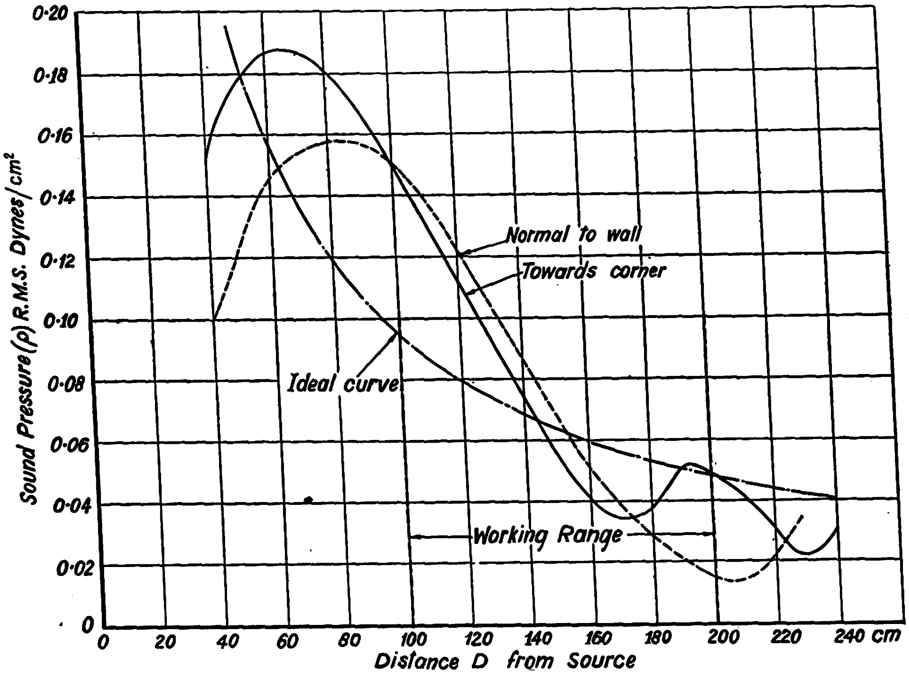

FIG. 21.—Pressure distribution curves in lined test room.

Frequency = 270 cycles per sec. Source at centre of room and 15 in. above floor-level.

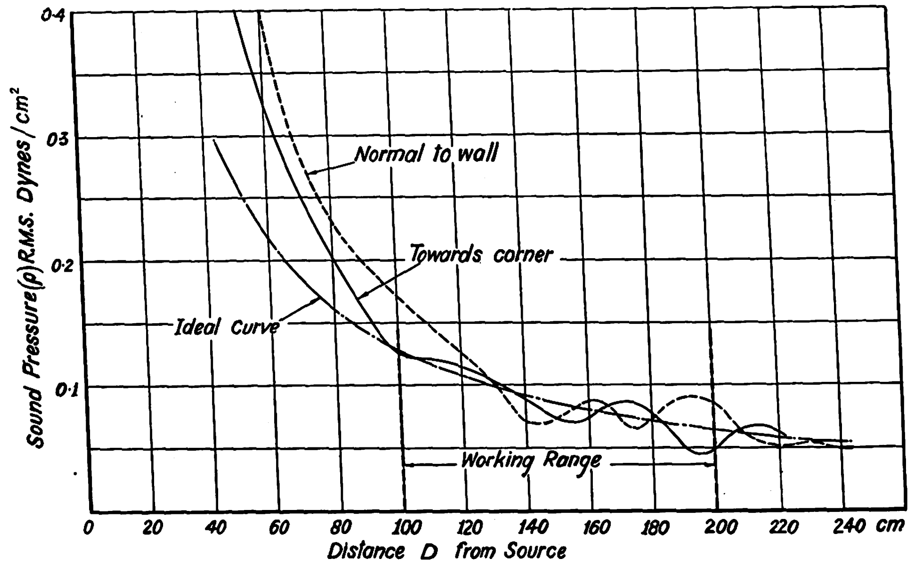

FIG. 22.—Pressure distribution curves in lined test room.

Frequency = 540 cycles per sec. Source at centre of room and 15 in. above floor-level.

located in the roof. If necessary, the noise of the fan can be eliminated by switching it off during a test. The generator room contains a separately excited d.c. generator mounted on a concrete block, and load resistances, so that suitable loads can be applied to a motor under test at speeds up to 3 000 r.p.m. The generator is coupled to the motor by a long shaft, mounted in ball bearings, passing through the double wall separating the test and generator rooms. The instrument room, the dimensions of which are 27 ft. 6 in. by 6 ft., provides accommodation for the sound-measuring apparatus (except the microphone), the control gear for the motor or other apparatus under test and for the loading generator. The fundamental standards for calibrating the measuring apparatus are also placed in this room. For heating this room the heaters are distributed in such a way as to avoid appreciable temperature gradients over the length of the Rayleigh disc tubes.

The site chosen for the building was a compromise between avoiding proximity to railway shunting sidings, factory buildings and a local substation containing a high-frequency alternator, and obtaining a conveniently central position. It was necessary to avoid not only acoustic disturbances but also electromagnetic disturbances from such apparatus as high-frequency induction furnaces and high-frequency oscillation generators and from the powerful oscillatory discharges associated with high-voltage testing.

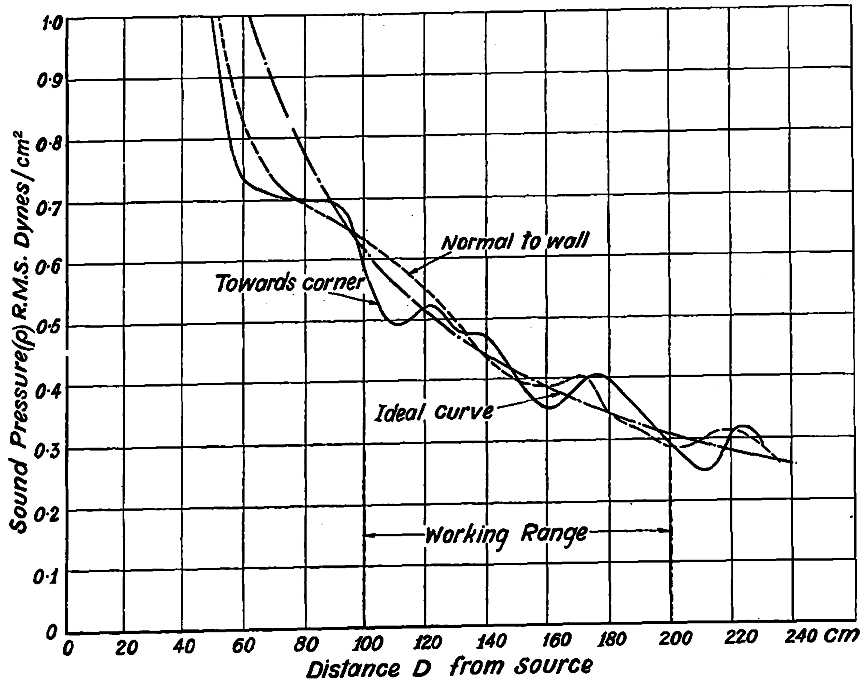

FIG. 23.—Pressure distribution curves in lined test room.
Frequency = 1 080 cycles per sec. Source at centre of room and 15 in. above floor-level.

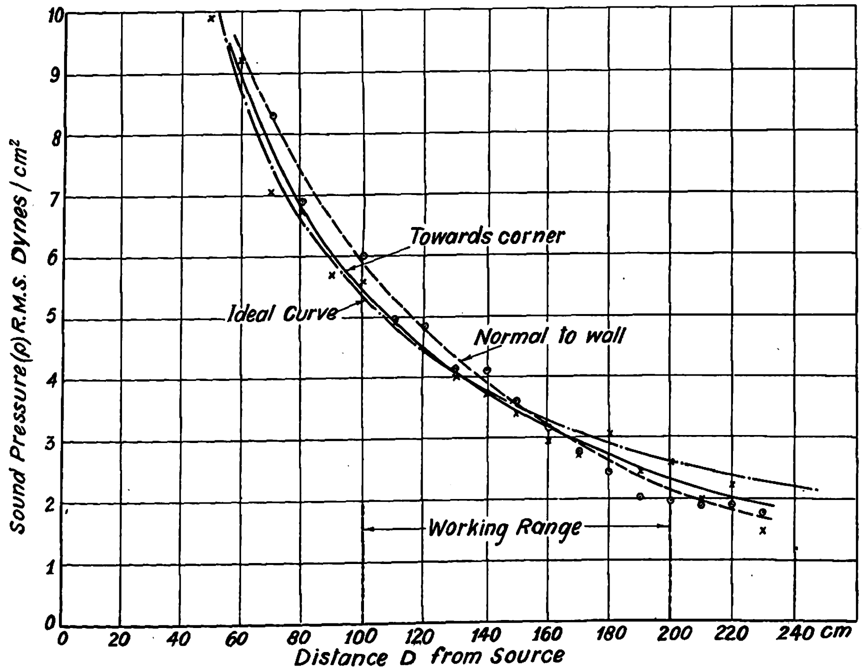

FIG. 24.—Pressure distribution curves in lined test room.
Frequency = 2 160 cycles per sec. Source at centre of room and 15 in. above floor-level.

The choice of a 10-cm lining of cotton waste for the test room was made as a result of Mallet and Dutton's work.* However, when the sound field due to a source hung in the centre of the room was explored it was immediately obvious that reflection effects were important, especially at low frequencies. An investigation into the reflection from different thicknesses of cotton waste was therefore commenced with a view to determining the best thickness to employ, having regard to economy and absorption. The Rayleigh disc and resonant-tube method seemed directly applicable to the problem, so it was chosen as the apparatus was all at hand. Tests were begun with a frequency of 292 cycles in the large calibrating tube with 2½ wavelengths between the reflecting pistons, one containing No. 4 microphone and the other the source exactly as in calibrating. The input to the source was measured and kept at that value throughout the tests. By taking preliminary readings of the Rayleigh disc and analyser galvanometer deflections, an incidental check was obtained on the microphone calibration and showed that it had not varied appreciably over a period of 6 months. The microphone and its piston were covered with a 10-cm layer of cotton waste, care being taken to keep the diaphragm free by a layer of copper gauze. It was found that the resonant frequency was unaltered, but the pressure and velocity deduced from the new readings were reduced in exactly the same ratio. Measurements were then made with 20 cm and 30 cm of waste and also with different densities of packing. In all cases the pressure and velocity readings agreed and the resonant frequency remained the same. In interpreting the results, which are given in Figs. 18 and 19, it is assumed that the initial wave from the source remains constant and that therefore the final pressure, which is the result of an infinite number of reflections from the pistons, is inversely proportional to the absorption in the tube.

In the first tests a constant density of 30 grammes per litre was kept while the thickness was varied up to a maximum of 30 cm. Fig. 18 shows how the ratio of the maximum velocity with the waste to that without varies with the thickness. The latter is necessarily rather indefinite but the graph indicates that 30 cm of such a packing would be necessary to reduce the oscillating velocity and pressure to 1/10th. The results of the tests on the tightness of packing are given in Fig. 19. They show that the absorption increases approximately with the density of the waste up to the limit of the tests, viz. 90 grammes per litre. This suggested a further test with thickness, using a higher density of 50 grammes per litre. The curve still indicates improvement up to the largest thickness.

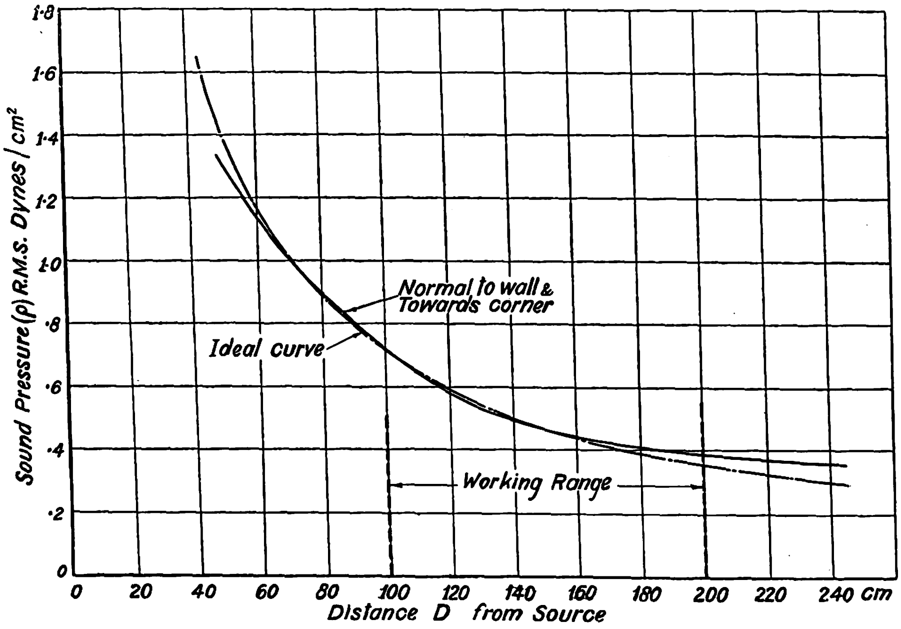

Fig. 25.—Pressure distribution curves in lined test room.

Frequency = 4 180 cycles per sec. Source at centre of room and 15 in. above floor-level.

It was obvious, therefore, that some compromise would have to be made, and finally a thickness of 20 cm was decided upon. A packing of approximately 50 grammes per litre made the total weight of waste nearly 1 ton; this figure was therefore adopted.

The packing on the walls and floor was first increased from 10 to 20 cm, that on the walls being pushed into the meshes of the wire netting so that when finished all the shelves and netting were covered with an unbroken layer of 10 cm of waste. On the floor several "stepping stones" of wood 15 cm thick were put where required to prevent the waste from being trampled down.

The work of plotting out the sound field due to a source suspended in the middle of the room was then repeated and a few typical pressure/distance curves are given in Figs. 20 to 25. These curves show that reflection effects have been largely eliminated at high frequencies but that they are still appreciable at low frequencies. Tests have usually been made at distances of 1 to 2 m, and as a result of these distribution curves a distance of 1·5 m has been standardized. All results, however, are referred to a standard distance of 1 m.

---

* See Bibliography, (34).

(10) Examples of Test Results.

In order to illustrate the kind of result that may be obtained on various types of apparatus, a few examples are given below. These examples have been taken quite at random and should not be assumed to be representative of their respective classes.

Example (1). *Tests on a small motor.*—The following test illustrates those made on small motors in the non-reflecting test room. The example chosen is a 10-h.p. induction motor operating from the 420-volt, 3-phase, 50-cycle mains and running light. As one would expect, the distribution of sound round such a machine is by no means uniform in all directions, so it is necessary to take readings on all sides. Readings were also taken at several distances, viz. 1·0, 1·5 and 2·0 m, to verify the rate of falling-off of the pressure. In view of the smallness of the machine these distances were measured from the centre of the casing. Fig. 26 indicates the component frequencies with their respective amplitudes in the four directions.

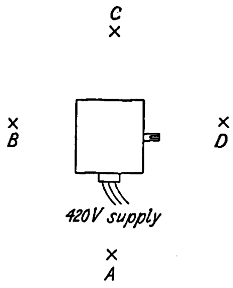

Fig. 26.—Diagram of sound field of a motor.

Readings taken at points A, B, C, D, all 1 m from centre of motor. The readings at A and B are almost identical, as also are those at B and D.

Readings at A		*Readings at D*	
Frequency (cycles per sec.)	Amplitude (R.M.S. dynes/cm²)	Frequency (cycles per sec.)	Amplitude (R.M.S. dynes/cm²)
225	0·625	100	0·07
360	0·37	225	0·235
524	0·18	310	0·27
590	0·18	394	0·35
670	0·18	590	0·12
1 640	0·10	1 120	0·12
		1 230	0·07
		1 640	0·06

Having obtained the components, the next step is to try to associate each one with some part of the machine. Since the sounds are peculiar to the rotation of the machine, each frequency is divided by the speed (revs. per sec.) of the rotor. A series of numbers is obtained which is very helpful in tracking the component sounds to their respective sources. For instance, in the case of this motor the following components are easily identified:—

Frequency of note	Frequency ÷ (revs./sec.)	Corresponding to
225	9	9 blades on fan
675	27	3rd harmonic of fan note
1 120	45	45 rotor slots
100	—	Vibration of punchings, twice supply frequency

As a check the fan was removed and another test taken. The 225- and 675-cycle components were absent.

Example (2). 1 000-*kW geared turbo-alternator set. Speed of turbine* 5 030 *r.p.m. Speed of generator* 1 000 *r.p.m. Distance of microphone from side of gear case,* 3·8 *m.*—Test carried out in large factory building in clear open space. Reflection effects were investigated and found to be not serious. The following values were obtained at full load and normal speed:—

Observation	Frequency (cycles per sec.)	Sound pressures (observed values)	R.M.S. dynes/cm² (aver. values; aver. corrected to 1 m)
A	2 710	2·37 to 2·75	2·56 to 9·7
B	1 610	1·04	1·04 to 3·9
	1 490	0·78	0·78 to 2·96
C	590	0·76	0·76 to 2·9
D	515	1·02	1·02 to 3·9
	474	1·25	1·25 to 4·7
E	360	1·17 to 1·4	1·28 to 4·9
F	240	2·94 to 7·6	5·28 to 20
G	190	0·7	0·7 to 2·6
	140	0·7	0·7 to 2·6

Observation A yielded a note of definite frequency, which slowly fluctuated in amplitude between the limits of 2·37 and 2·75. B consisted of a band of frequencies extending from approximately 1 610 to 1 490 cycles, the amplitudes corresponding to these frequencies being 1·04 and 0·78 respectively. C gave a definite and steady note, D gave another band of frequencies and E a definite frequency but slightly fluctuating amplitude. F was of considerable and variable amplitude but of low frequency, while G consisted of a general low-frequency rumble.

Example (3). *Test on a commercial horn-type loud-speaker.*—The sound-measuring apparatus and testing laboratory were developed primarily for tests on machines, but the present example illustrates the application of the methods and technique to another useful purpose. The comparison of loud-speakers in the past, as regards sensitivity and type of response curve, has been largely a matter of opinion. It is easy, with the apparatus described, to measure the response of any loud-speaker in a sensibly non-reflecting room at all important frequencies and to give the answer in absolute units. The curve of response against frequency, such as is given in Fig. 27 for the attracted-diaphragm type of loud-speaker tested, then provides a definite fundamental basis for comparison. There is very little doubt that, in a year or two when people have been educated to the sight of the utterly inadequate curves for their favourite loud-speakers, the makers of the better-class instruments will publish response curves just as the intervalve transformer manufacturers have done recently.

The fact that the loud-speaker tested would satisfy a large proportion of listeners is a striking testimony to the adaptability of the ear. Notes in the lower half of the piano range are heard largely as harmonics, the ear subconsciously supplying the diminished or absent fundamentals. It is also interesting to note that when this loud-speaker was supplied with 50-cycle currents no output at that frequency could be detected but, due to non-linearity, frequencies of 100 and 150 were generated and could be detected.

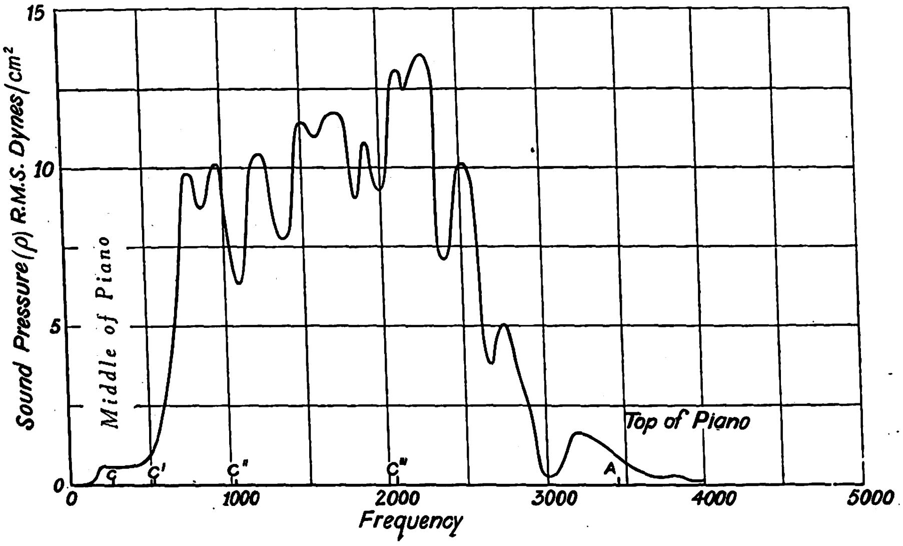

FIG. 27.—Response curve for a loud-speaker of attracted-diaphragm type.
Input current = 1·6 mA. Corrected for reflection from microphone. Measurements made at 1·5 m and reduced to 1 m.

If preferred, of course, the test could be made in conjunction with a particular loud-speaker valve, but in the present example a constant current of 1·6 mA was kept in the operating coils.

Fig. 28 shows the wave-form of sound emitted by a motor-generator set, and illustrates the complexity and non-periodic character of such waves.

(11) THE ASSESSMENT OF TOTAL NOISE.

It is generally accepted by psychologists that the ear adapts its sensitivity to the strength of the sound which acts on it. That is, for a loud sound the ear automatically de-sensitizes itself, afterwards regaining its sensitivity for small sounds. It must be very largely due to this self-preserving capacity that the ear has such a remarkable range of sound pressures to which it responds. At 1 500 cycles this compass of the ear is 5×10^6 in pressure units or 25×10^{12} in energy units.

Another consequence of this automatic regulation of the ear is to make equal geometric increments of sound energy appear like equal arithmetic increments in loudness. If, therefore, we take the logarithms of the intensities of two pure notes of the same frequency, then the difference between the logs is a measure, to some "sensation" scale, of the difference in loudness of the two notes. Further, if one of the notes happens to be on the threshold of audibility, then the difference between the logarithms of the two intensities can represent the absolute strength of the louder note on our arbitrary sensation scale.

In choosing suitable units for this new scale, telephone engineers have been guided by their previous standard, the "800-cycle standard mile." Instead, therefore, of taking just the logarithm to the base 10 of the sound energy, a unit 1/10th as large has been adopted and this corresponds roughly to the old standard. The name "decibel" has been given to the new unit to commemorate the inventor of the telephone, Graham Bell.

Since we work in sound pressures the difference in loudness between two pure notes of pressures p_1 and p_2 dynes/cm² is $20 \log_{10}(p_1/p_2)$ decibels.

Taking for p_2 the minimum audible pressure at the frequency considered, the loudness level of the pressure p is $20 \log_{10} (p_1/p_{min.})$ decibels.

Here we have a method of assessing the loudness of notes of different amplitudes but the same frequency. This latter restriction is important as the variation in minumum and maximum audible sound pressures at different frequencies is enormous.

In trying to compare the loudness of notes of different frequencies it seemed reasonable to the authors to make a sound corresponding to the maximum audible pressure at any frequency to be represented by 100 and a sound on the threshold of audibility by zero on the loudness scale. That is to say, they divided the range between minimum and maximum audibility into 100 equal ratio steps, calling these equal increments on a sensation scale.

The "relative loudness" or "nuisance" figure for a sound of pressure p dynes/cm^2 (R.M.S.) is therefore given by $100 \log_{10} (p/p_{min.}) \div \log_{10} (p_{max.}/p_{min.})$, where $p_{min.}$ and $p_{max.}$ are the minimum and maximum audible sound pressures taken from Fig. 1.

Since the ordinates of Fig. 1 are on a logarithmic scale, it is easy to get a rough idea of the loudness figure corresponding to a given pressure p at a frequency f by plotting the point (f, p) and noting into what proportions it divides the intercept between the two curves. If the point is half-way up the intercept the loudness figure is 50, if one-quarter of the way, 25, and so on. It is possible to mark the contours corresponding to loudness figures of, say, 60, 40 and 20 on Fig. 1 to facilitate this quick estimate.

Experience in testing a large number of machines of all sizes and types has given the authors a certain amount of confidence in this tentative loudness scale. A preliminary aural estimate of the most offending component of a noise is always confirmed by a high loudness figure where the results of an analysis are available.

Even if this loudness scale is accepted for the moment, the problem of assessing the total loudness of a number of components of different frequencies still remains. A solution of this problem has been proposed by J. E. Steinberg,* but the authors have not yet had an opportunity of judging how far his methods can be applied.

There is one case which does not lend itself to the above treatment. This exception is a band of frequencies such as is sometimes produced by windage. When analysing such a noise a continuous deflection is obtained over the whole band of frequencies, and the loudness figures deduced from the readings are much larger than one would expect. It is thought that this is due to the fact that the analyser is sensitive to a narrow band of frequencies, roughly 0·5 per cent wide, whereas the results are given just as if all the energy in that band were concentrated on the central frequency. The apparent energy density is therefore much greater than that which really exists at the central frequency. Any results given on such a band of frequencies are therefore peculiar to the resonance curve of the apparatus used, whereas measurements on pure tones and noises which can be analysed into distinct pure tones are independent of the apparatus used. Since writing the above the authors' attention has been drawn to an article by B. A. Kingsbury † in which he describes his experimental determination of comparative loudness. He deduces that the loudness of pure tones from 700 to 4 000 cycles is very well represented by the number of transmission units or decibels above the threshold value. For lower frequencies he found that the loudness increased faster than the transmission units or decibels above minimum audibility. These conclusions support the expression for loudness given by the authors, since the ratio of the maximum to the minimum audible sound pressures is nearly constant from 700 to 4 000 cycles and decreases rapidly at lower frequencies.

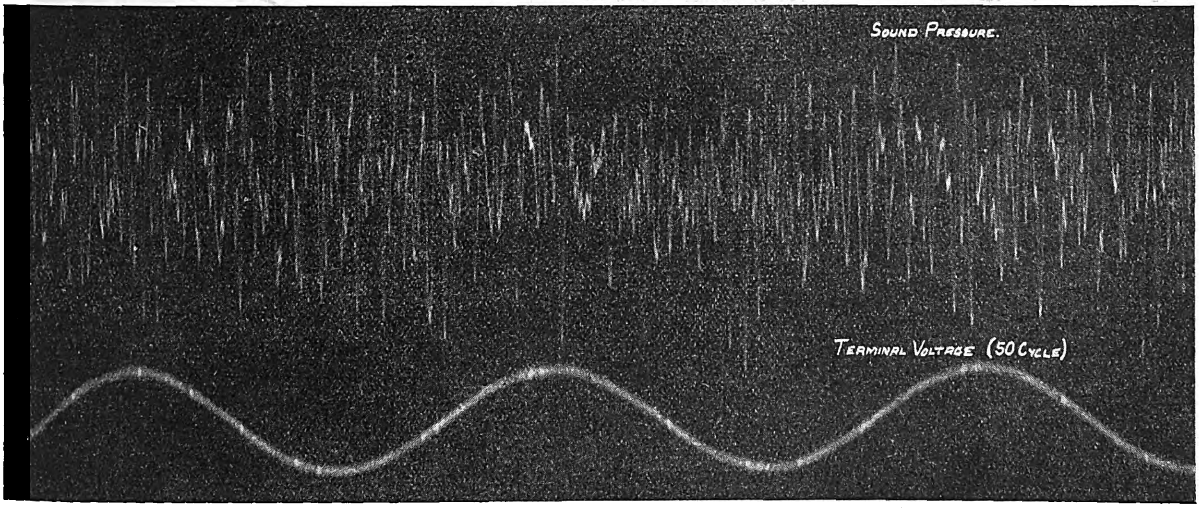

Fig. 28.—Wave-form of sound emitted by a motor-generator set.

It is evident that the assessment of the loudness of complex sounds is a subject of great importance and difficulty. It demands a knowledge not only of the physical qualities involved but also of the related physiological and psychological effects.

(12) Further Fields for Acoustical Measurements.

The experience gained by the authors in the testing of various machines has suggested that a modified form of sound-measuring apparatus might be employed to solve numerous other problems. A brief discussion of a few possible applications may therefore be of interest to those concerned.

The vexed question of "street noise" forms the subject of periodical attacks by the Press, but the difficulties in the way of fixing noise limits and enforcing them have prevented much progress from being made. To take a record of such noises the amplifier and oscillograph are directly applicable, but unfortunately there is the difficulty of analysing the oscillograms obtained.

---

* See Bibliography, (24).

† *Ibid.*, (26).

A new apparatus of a more portable and self-contained type is therefore being designed and it is hoped that it will be possible to analyse a noise into all its components and measure their frequency and amplitude in approximately 1 minute. Motor vehicles and tramcars could be driven round a circular track at a constant speed with a central microphone always pointing towards the machine under test. In this way noise pass limits could be fixed and border-line cases judged on a definite quantitative basis. It is certain also that the information obtained would be of great help to the designers of such machines in producing quieter models. In view of the rapid advance in civil aviation it is more than probable that, sooner or later, similar methods will have to be applied to reduce the noise emitted by aeroplanes and airships.

The investigation of the sounds emitted by musical instruments constitutes a vast field for acoustical measurements. The excellence, from a tonal point of view, of English organs is known all over the world. This high standard has been gradually achieved by trial and error over a period of centuries. It is probable that the precise and detailed information that acoustical measurements can furnish would be of considerable assistance to organ builders. With an apparatus of the kind described in this paper the pitch and intensity of the fundamental tone and of the partials of an organ pipe could be measured with ease, and the effect of any modification in the structure of the pipe, the wind pressure or other condition immediately ascertained. The apparatus would not, of course, indicate tone quality from a musical point of view, of which the ear, in conjunction with a high degree of musical sensibility, must always be the judge. The measurements would, however, show quantitatively the physical constituents of any tone quality and would assist in the accurate reproduction of a given quality in pipes of the same nominal quality and pitch, and in preserving a uniform tone quality in a set of pipes covering a certain compass.

(13) Conclusions.

In order to keep the paper within a reasonable length, the authors have not attempted to deal with the whole subject of the noise emitted by machines but have confined themselves to a discussion of methods of measuring noise emitted by stationary machinery, which is a necessary preliminary to any systematic investigation of the subject. Since the paper was written, a wide experience has been gained in the interpretation of the results of measurements on machines of various types, their correlation with the design data of the machines and the measures which are effective in removing excessive noise. The discussion of these matters is beyond the scope of the present paper.

In conclusion, the authors wish to acknowledge their indebtedness to Mr. J. S. Peck and Mr. A. P. M. Fleming, C.B.E., for their interest and support throughout the research, to Mr. R. Johnson, to whom the inception of the work was due, and to Messrs. D. B. Hoseason and J. M. Newton for ready discussion and co-operation. They also wish to thank their colleagues of the Metropolitan-Vickers Research Department for assistance in the experimental work and in the construction of the measuring apparatus.

They also wish to acknowledge the permission of the Metropolitan-Vickers Electrical Co., Ltd., to publish the paper.

Characteristics of the Ear.

DISCUSSION BEFORE THE INSTITUTION, 7TH NOVEMBER, 1929.

Prof. E. Mallett: Some years ago Dr. Dutton and I constructed a small sound chamber for use in measuring the overall efficiency of a telephone receiver. We were not troubled by sound reflection from the walls of our chamber, which were lined with cotton waste. The authors were guided by the results we obtained, and they did not get a satisfactory solution. We, however, were working at frequencies of from 700 to 900 cycles per sec., and from the authors' results it will be seen that we were fairly safe over that range. It is at lower frequencies that reflection troubles in the sound chamber become serious. The authors, by working down to 100 cycles and up to 4 000 or 5 000 cycles per sec. with one piece of apparatus, have carried out an important and difficult task. The use of the moving-coil movement of the loud-speaker as a microphone, instead of the more usual condenser microphone, is a bold step. At first glance one might think that the moving-coil movement was unsuitable; in America the condenser microphone is always used. It is interesting to note that the moving-coil system proved so successful. The amplifier presents no real difficulties, except that one must be very careful that the coupling condensers are of very high insulation resistance. If the insulation resistance of a condenser falls to 20 megohms, the next valve will probably cease to function correctly owing to the positive potential thus produced on the grid. The coupled-circuit method of overcoming difficulties due to the frequency variation of the machine under test is ingenious, and the authors are to be congratulated on it. Prof. Miles Walker made a suggestion for harmonic analysis, in which the machine itself was used to give the frequency of the auxiliary current necessary for measurement. That, one would have thought, would be a suitable method also, except that the authors have found frequencies which are not harmonic. There must be some sort of shock excitation of parts which vibrate at their natural frequencies, which are not necessarily harmonic. The influence of the size of the microphone on the proportion of the wave reflected and the correction to be applied to the pressure reading has for a long time required investigation, and the authors are to be congratulated on carrying out an opportune piece of work. Returning to the sound chamber, Figs. 18 and 19 can be arranged a little differently, so as to indicate the best density at which to use a given mass of cotton waste. Fig. A shows two curves, (i) reproduced from Fig. 19, showing the sound absorption with various weights of waste packed into 10 cm thickness, and (ii) the absorption for the same weights of material but at a thickness in each case giving a constant density of 30 grammes per litre. It is seen that the looser packing is the more effective. With 250 grammes of material the ratio with the loose packing is about half that with the tight packing. Since this clean cotton waste is expensive, this is an important consideration. These curves apply only to a frequency of 292 cycles per sec. It would be interesting to see similar data at other frequencies.

Mr. D. B. Hoseason: The paper deals with one particular method of measuring noise emitted by machinery. It may save other investigators a little time if mention is made of the work which had already been done before the assistance of the authors was obtained. There are two fairly well-known methods of assessing and comparing noise. First there is the shunted telephone method, referred to in the paper, which has been used both in Germany and in America with, we are told, a certain measure of success. This device was investigated fully, and the conclusion arrived at that it was not satisfactory on account of the periodic characteristics of the telephone. These make comparison of the results obtained from machines emitting noises of different frequencies quite useless. An alternative method which has been used in the United States is that of comparison with a standard machine. A selected machine is adopted as a standard and placed in a sound-proof room. The machine under test is placed in another sound-proof room, and the noise from each received in the two ear-pieces of a pair of headphones. The ear-piece corresponding to the machine under test is shunted to obtain the comparison. This method has the same defect as the first-mentioned scheme. Another alternative which was tried, and with which, again, we were not very successful, was to use a dictaphone. We endeavoured to take records of the sound emitted by various machines, with the idea of filing these and listening to the dictaphone records of a particular machine built, say, 2 years previously, and one which was on test in order to discover whether it was more noisy or less noisy than the previous machine. Eventually we sought the assistance of the authors, and in spite of the troubles that have been experienced the results embodied in the paper are, to say the least, highly satisfactory. A matter that intrigues me is the question of the influence of harmonics on the fundamental sound-wave—or what really seem to be not so much harmonics as a mixture of noises of several different frequencies. The authors refer to Knudsen's work and state that several tests have been made presumably by listening to a fundamental note and then adding known harmonics to it. Has Knudsen stated the amplitude of the harmonics and given any definite frequency relation between these and the fundamental? Some specific figures would be of assistance. Later in the paper reference is made to the work now being done by Steinberg, and it would be interesting to have details of his methods. The intermingling of notes of several different frequencies is at the present time the most urgent and difficult problem that we have to face in this matter.

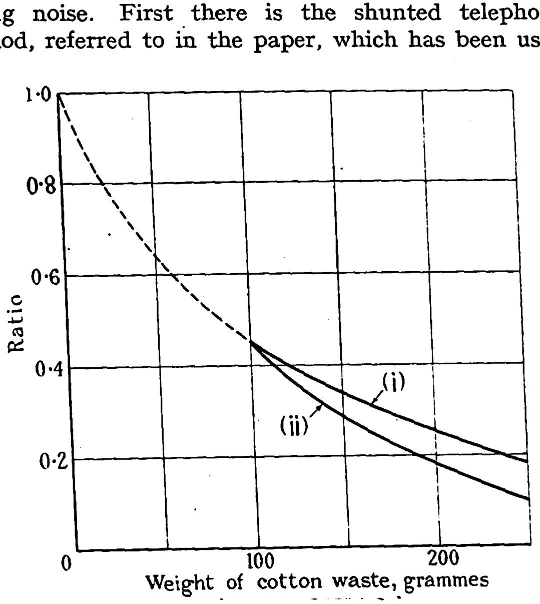

FIG. A.

Mr. A. J. Aldridge: This paper is an indication that at least one firm is at last making an attempt, on sound lines, to tackle the problem of noise and its elimination. It deals with matters on the border line of physics and engineering, and to many of us these border-line cases are more interesting than those dealing with purely engineering questions. I am particularly interested in the earlier part of the paper which deals with the measurement of sound. The authors have adopted an electromagnetic microphone to pick up the noises. An instrument of this pattern can be made fairly robust and this is an important consideration for a works instrument. It will, however, usually be of greater bulk than a condenser transmitter, and would, I expect, be rather difficult to screen when used near heavy-current machinery. Have the authors experienced any trouble due to this cause? On page 103, the authors state that they selected a microphone of this type because its performance could be calculated. They make this calculation and then proceed to check it by a direct calibration, and accept this method of calibration since the results of both methods agree reasonably. This appears to be "putting the cart before the horse." The calibration method is much superior to the calculation method. The method shown in Fig. 7 for calibrating microphones was first proposed in 1926 by Mr. W. West, of the Post Office Research Station, and has been largely used by us since then. We have several tubes in use designed for from 50 to 6 000 cycles per sec. Independent tests of this method against two others have shown it to be thoroughly reliable, and the only point to bear in mind is the fact that the "use" and "calibration" conditions are different. The authors deal with this matter on page 109 and subsequent pages. The authors do not give much information as to the results of their tests. It would be interesting to know if they have arrived at any values of permissible sound pressures for machinery for noises of various types, and also what measure of success they have reached in reducing the various noises when they have located their sources. It may be of interest to quote a few results recently obtained in connection with the noise in a city office. The occupant complained that it was impossible to work with the windows open and that even when they were shut the street noise was objectionable. Measurements were made with a calibrated condenser transmitter, the output of which was read for some hours on two microammeters in series, one being a slow-moving recording instrument, to average the results, and the other a quick-moving instrument, giving the peak values. It was found that the energy density was much the same in all parts of the room and with the windows open average figures of up to 0·5 dyne per cm^2 were recorded. (The pressures at the threshold of audibility vary from about 0·01 at 200 cycles per sec. to 0·005 at from 1 000 to 5 000 cycles per sec.) The fitting of a false ceiling of ½-in. felt 5 in. below the true ceiling reduced the pressures by about half. The noise was practically all found to occur at frequencies above 500, and as the ear reaches its maximum sensitivity just above this point, the improvement, as tested by ear, is greater than the figures indicate. Tests were also made in the modified room of the noise from a single typewriter. Values of up to about 0·5 dyne per cm^2 were found, the frequency of the noise being almost entirely above 2 000 cycles per sec.

Dr. L. E. C. Hughes: I am particularly interested in these specialized methods for the measurement of sound. When listening to a sound one hears the direct sound and the reverberation, and I should like to know if the authors considered a reverberation method, since noises usually reach us as reverberatory sound, and in any case it is the total sound radiated that is required in this measurement. Having decided to measure the direct sound, the authors would have saved considerable time by adopting the condenser transmitter, which, although expensive, is ideally suited for the desired measurement and has been extensively used in acoustic research for many years. The calibration of the condenser transmitter is performed with the thermophone, which generates a known excess pressure on the diaphragm. When placed in the open sound field, the excess pressure is, as indicated by the authors, augmented owing to the disturbance. I once thought that the unknown error might be circumvented by placing the condenser transmitter in the centre of a large baffle or wall. We then know that the excess pressure upon the diaphragm is exactly double that in the free wave for every frequency, and the thermophone calibration is applicable without correction. This wall would form one side of the sound chamber; reaction on to the source is negligible under these conditions. The best method using the condenser transmitter, or any other transmitter, is to compare its output when subjected to a sound with its output when a known electromotive force of the same frequency is injected into its earth lead. Not only is the calibration of a high-grade amplifier eliminated, but the circuit is exactly the same as that used in the thermophone calibration, and there can be no doubt in the interpretation of the measurements. The authors appear to have aimed at a high degree of accuracy in their sound intensity measurements; excess pressure measurement to within ± 10 per cent, corresponding to ± 1 decibel, is ample in this connection. Condenser transmitter calibrations are given to the nearest ½-decibel, which is adequate considering normal daily variations in such transmitters. With regard to the sound chamber, it is comparatively simple to measure the standing waves from one of the walls and compute the coefficient of reflection. In Prof. Mallett's 9-ft. cube lined with 4 in. of loose cotton waste on netting, I found the coefficient to be 6 per cent at 400 cycles per sec. and about 1 per cent above 800 cycles per sec., which is much less than for any other material. In the chamber described by the authors, a definite reduction in the reflection coefficient at low frequencies would result from the provision of a hollow space behind the cotton waste, in accordance with the principle that if cotton waste is to be used to absorb the motion of the air particles, it should be placed where the particles are moving, and not against a hard wall where the motion of the particles is practically nil. With regard to the curves in Figs. 20 to 23, it is stated that the source is 15 in. above the floor. Now it can be shown mathematically that on a line of symmetry towards a corner there is an augmentation of the apparent intensity due to reflection, but no wave-effect such as is exhibited by the curves. It seems, therefore, that the standing-wave effect is due to the wave reflected from the floor, and that better results would be obtained by locating the source at half the height of the ceiling. This observation applies also to the machines which are tested for noise.

Dr. A. H. Davis: At the National Physical Laboratory we have had to deal with various phases of noise recently; for instance, in assisting the Aeronautical Research Committee with the study of aircraft noise. Naturally, sound analysis is receiving attention, but I have also made several observations by ear, using a simple sort of noise meter which is proving, I think, to be of value. With this work in mind, the subject on which I wish to dwell for a few minutes is the assessment of noise, but I should first like to make a few comments regarding the instrumental side. The identification of sources of noise is, as the authors point out, facilitated by knowing the frequencies of the components, and so an analyser is necessary. Apparatus of a general type resembling that described by the authors has been used for several years in connection with the physical analysis of sound and noise, and, in addition to the papers mentioned by the authors, perhaps papers by Snook,* in 1925, and Firestone,† in 1926, on automobile-noise measurement may have some value for reference. A previous speaker has mentioned that the Americans have been investigating by a somewhat similar method the noise emitted by machinery; and Spooner and Foltz ‡ have recently published a paper dealing with tests on the noises in electrical apparatus, using somewhat similar apparatus, with certain differences of detail; in particular, they do not use double tuning. The method of Grutzmacher § is so promising that I should like to refer to it, though the authors will no doubt point out that it is inapplicable in certain cases. It enables each component of the noise to be studied in turn by heterodyning it with a pure exploring note of variable frequency. It is a somewhat indirect method, but its outstanding features are that it gives very sharp selectivity and in suitable circumstances is exceptionally convenient. For instance, the complex sound emitted from a loud-speaker when actuated by the ordinary 50-cycle a.c. supply mains, and adjusted so that the diaphragm rattled against the pole pieces, was analysed by Mr. Fleming and myself in a few minutes, some 30 definite overtones of the fundamental being observed. The method was adapted by Grutzmacher to be self-recording on a photographic drum, and a complete record giving the intensity and frequency of the component sounds can be obtained, he states, in a few seconds. The selectivity, of course, is marked. As the authors point out, where the noise is not of fixed pitch too great a sensitiveness to frequency reduces the value of the analyser; but recently Salinger has suggested improvements * which may be of assistance in this direction. The authors have dealt with this question of selectivity and, to meet the needs of their own work, have ingeniously adopted double tuning in order to obtain a flat-topped selectivity curve. Turning to the assessment of noise the position, as I see it, is as follows. We do not yet know how to infer the loudness of a complex sound from the analyser results. We know that the matter is complicated. The formula to which the authors refer, namely that advanced by Steinberg, was quite intricate, but I suspect that even this has not proved applicable outside the range of experiments on which it was based. It is 4 years since Steinberg's paper was published, and recently a member of the laboratory to which Steinberg belongs wrote: "Attempts to develop methods of calculating loudness which have a general application have not yet been successful." † The Steinberg formula is apparently being gradually abandoned. On the one hand, therefore, we feel that we must take physical measurements in order to obtain analyses which will be useful in tracing the sources of components, and which will give a permanent record; but on the other hand, since our knowledge is incomplete, I think that we ought sometimes to try to assess the loudness itself by instrumental means. From that point of view I do not agree with setting up a relative " loudness " or " nuisance " figure from the analyser at this stage, as the authors appear to suggest. I do not agree with the scale which they show; I think we know, even now, that pure tones with the same relative loudness figure on this scale would not be equally loud. Further, the authors themselves found their procedure somewhat troublesome when dealing with such sounds as the band frequencies which result from windage. In my opinion, for the present at any rate, the loudness or nuisance term should be left open for methods which attempt in some way to assess loudness itself. A method I have used, largely on aircraft work, with promising results is to produce a pure note of standard pitch in a telephone ear-piece, and to adjust its loudness until it appears to be as loud as the noise observed. That may seem troublesome, but in my experience different observers tend to get the same result, and over a period of some months I have found the method substantially consistent and useful. With such a method one can thus say that the noise appeared to be as loud as a pure note of standard pitch exerting a pressure of a certain number of dynes per cm^2 on the ear. This seems to be the tendency to-day in specifying loudness—to refer it to the loudness of a standard note. Alternatively, or, as I prefer, in addition, one can say that the noise was observed to drown this standard note when the intensity of the latter was at some lower figure. I think that both statements are useful. The equality method has been used by Barkhausen in Germany, while the masking method has received more attention in America. I suspect that the energy ratios of the test note in the equality method bear a more nearly linear relation to the energy ratios of the observed noise than is the case with the masking method, for with the latter method it is well known that a certain amount of sound is usually required before any appreciable masking appears at all. On the other hand, masking is not to be ignored, for it is used in everyday life to express loudness; people say "You could hear a pin drop" or "You could not hear yourself speak." Those are masking standards. With regard to this method of balancing a complex noise against a pure note, I set out quite prepared to abandon it, but I have been somewhat impressed by its usefulness in suitable cases. I feel, therefore, that observations of this kind are sometimes desirable to supplement analyses, and that one should drop the terms " relative loudness " or " nuisance " in connection with the percentage figures suggested in the paper, or at any rate defer them until the figures suggested have a better basis than they have at present.

Mr. G. C. Marris: After reading the title I was a little disappointed to find that more than half of the paper consists of a rather detailed summary of matter relating to general acoustics of which a good deal has already been published, and it is not until two-thirds of the way through that there are some figures relating to actual results obtained on the machines. These results are certainly interesting as showing what may be expected in the future. The authors have given some results obtained on a turbo-generator. Can they give us an interpretation of these results? I think that the high frequencies are very important in connection with machine noise, especially in some of the smaller machines. I gather that the authors have concentrated on the lower frequencies. Above 3 000 cycles, however, noises which are important do seem to occur, especially as in that region the ear is still very sensitive. In the paper by Grutzmacher, to which Dr. Davis has referred, are some very interesting figures showing the spectrum of the noise from, I believe, some small domestic machinery, such as vacuum cleaners. The authors advocate the use of the moving-coil type of pick-up, but it certainly seems to me that it has drawbacks, and I do not feel convinced by their arguments. The calibration curve given in Fig. 9 is rather complicated to work to, and with such resonances and cut-off points it seems to me that the record of transient sounds must be rather distorted, though possibly these are not very important in every case. Early in the paper the authors state that the ear is not sensitive to phase displacement. That is true, but it applies only to the steady state; for the transient condition it would appear somewhat important to obtain a record, correct as to phase, through apparatus which has a linear frequency characteristic. If one assumes that an accurate analysis of sound is important in tracing the source of noise, and in studying the performance of acoustic apparatus generally, one would seem to require recording apparatus having a really straight frequency characteristic, and not an irregular one corrected by a calibration curve. As to the use of condenser transmitters, certainly our experience has not shown that there is difficulty in getting adequate sensitivity, or that low-capacity leads of a reasonable length cannot be used. It is possible to connect one stage of the amplifier right up against the microphone and to remove the rest of the amplifier to a distance. I was somewhat disappointed to find that the authors' moving-coil microphone had no greater sensitivity, judging by the figures given in the paper, than the condenser type. The authors state that they used specially purified cotton waste; it would be useful to know what form the purification took. I have not studied closely the analysis of the movement of the moving-coil microphone, but there appears to be no allowance for the "added mass" of air on the diaphragm. I am not clear whether, in the case with which the authors are dealing, that is actually of importance.

---

* *Elektrische Nachrichten-Technik*, 1929, vol. 6, p. 293.

† "Speech and Hearing," p. 244 (Macmillan & Co., Ltd.).

Mr. W. West: Why do the curves in Fig. 10 not show proportionality between wavelength and diameter of baffle? For example, the 540-cycle curve reaches the ratio 2 for a 30-cm diameter baffle, while the 270-cycle curve reaches this ratio at 50 cm and not at 60 cm; the 1 080-cycle curve at 21 cm, not 15 cm, and so on. The authors' method of adding baffles to the microphone involves two considerations which are, I think, of interest, though probably not of importance in the present case. The addition of a baffle to the microphone may alter, first, the mechanical impedance of the diaphragm and, secondly, the rate of emission of sound energy from a source of constant strength. The first effect might be important only where there is resonance, when the mechanical reactance of the microphone is small, i.e. on the steep parts of the microphone curve (Fig. 9). The fractional change in the rate of emission of energy from a small source, distant x cm from a large baffle, is $(\sin 2kx)/2kx$: numerically, when $x = 150$ cm, this does not exceed 10 per cent at frequencies greater than 200 cycles per sec. The authors contemplate the investigation of transient sounds with their apparatus; are they satisfied with the characteristic of their microphone for this purpose? There appear to be somewhat undamped mechanical resonances which would blur the form of the transient by their free periods of vibration. The relative loudness figure is based on the threshold of audibility; this implies that the loudness is judged against a background of silence. I think it has already been established that the effective loudness of a sound will depend on the character as well as the magnitude of the background against which the sound actually is heard.

Messrs. B. A. G. Churcher and A. J. King (*in reply*): We are glad to have Prof. Mallett's confirmation that, in fixing the thickness of the cotton-waste lining to his testing chamber at 4 in., he only wished to ensure that reflection was negligible at frequencies of about 800 cycles per sec. and above. With regard to our use of the moving-coil type of microphone we are fully aware of the advantages of the condenser type, but we do not wish to be tied to any particular type of instrument. The calibration of the moving-coil instrument is very constant and when it is used with a frequency analyser, which is the case with practically all our work, the variation of response with frequency is no inconvenience. With regard to the possibility of low insulation-resistance in the amplifier coupling condensers, this contingency and any other which may affect the amplification is covered by the device, which is embodied in the amplifier, by means of which the amplification can be checked at any time in a few minutes. With regard to frequency analysers of the Miles Walker type, it must be remembered that we have set out to deal with a great variety of engineering apparatus, both electrical and mechanical. It cannot be assumed that a synchronous supply is available, and, moreover, many acoustical frequencies are observed which are not functions of any electrical or rotational frequency. As Prof. Mallett suggests, parts of machines vibrate at their natural frequencies by shock excitation, and these frequencies are not necessarily related to any electrical or rotational frequency. We are much interested in Prof. Mallett's rearrangement of our reflection curves for cotton waste, which demonstrates a very useful point regarding economy in the use of the waste. In arranging our test room we had to place a limit on the thickness of waste we could use and then obtain sufficient absorption by using as great a density as possible.

Mr. Hoseason has given a brief but interesting survey of comparatively simple methods of comparing noise. While attractive on account of their simplicity and cheapness, none of these methods attempts to analyse noise or give noise values in terms of any definite or reproducible standard. Both these requirements must be met before any serious study of noise problems can be undertaken. With regard to the effect of the addition of harmonics to fundamental tones in Knudsen's work, it appears from his paper that the amplitudes of the harmonics are small compared with that of the fundamental. With regard to the theoretical work of Steinberg on the assessment of total noise, we fear that the subject is too complex to be dealt with here. We fully agree that the placing of the assessment of total noise on an adequate experimental basis is a very urgent matter and we hope to give attention to it in the near future.

Mr. Aldridge's question about the screening of the moving-coil microphone is dealt with in the paper. The earthing of the magnet system provides electrostatic screening, and the switching off of the electromagnet field enables electromagnetically induced voltages to be detected. With the microphone 1·5 metres or more from the source, there is seldom any trouble from interference. Referring to calibration methods, we are not under any misapprehension regarding the relative accuracy of the Rayleigh disc method and the calculation of the response curve of a mass-controlled microphone. Our object in comparing the results of the two methods was to ensure that no large error was present in our procedure in using the Rayleigh disc; it was not to confirm the principle, which has been established beyond question. The subject of calibration is so important that an independent check, even if only a rough one, is of great value. We are interested to know that development work has been proceeding at the Post Office laboratories concurrently with our own on the use of the Rayleigh disc in a closed resonant tube. The only indication we have had of the Post Office work on these lines has been a brief reference to the use of tubes down to 50 cycles per sec. in Mr. West's paper* this year, which, of course, appeared long after the completion of our work, which was submitted to the Institution in December 1928. With regard to limits for permissible noise in machinery, the discussion of this matter is beyond the scope of the present paper. We are greatly interested in Mr. Aldridge's observations on the noise in an office due to street traffic. The results would be difficult to interpret in terms of loudness in the absence of more detailed information on the frequency spectrum.

In reply to Dr. Hughes, we feel that many of his remarks arise from a want of acquaintance with the practical limitations which arise in dealing with machinery. As our aim is to make our results of general application it is necessary to avoid any dependence upon the reflecting properties of a test room. As indicated in the paper, we wish our results to be equivalent to those which would be obtained in free space. Apart from the fact that reverberation involves reflection, we are unable to see how reverberation methods could be applied to the analysis of complex sounds emitted by steadily running machinery. With regard to the use of the condenser transmitter, the contention that this instrument is ideal for our purpose is debatable. We have found the moving-coil instrument very satisfactory for our conditions. The importation of a calibrated condenser instrument would not have avoided the problem of absolute calibration, as it was essential for us to be able to check the calibration of our apparatus at any time. When we started the work in 1926, the calibration methods of which descriptions had been published did not satisfy us and we decided to attack the problem on our own lines. The general experience gained, and the fact that the method of using the Rayleigh disc in a closed air-column has arisen out of the work together with the method of correcting for the effect of the microphone dimensions, have, we think, amply justified the course we have taken. In general testing, the deliberate exclusion of reflection rules out the use of a large reflecting baffle. Moreover, a few experiments in the early stages of the work showed that multiple reflections were set up between the baffle and the source, which is not, in general, of negligible dimensions. Referring to the method of avoiding complete calibration of the amplifier and frequency analyser by injecting a known e.m.f. into the microphone circuit after each observation, this may be " the best method " for some circumstances which Dr. Hughes has in mind; but for the conditions we have to meet it would greatly retard the taking of observations and is in fact totally unnecessary, as checks made from time to time have shown that the overall calibration of the amplifier and frequency analyser is constant to 2 per cent. The procedure of calibrating after every observation appears to amount to an admission of inability to construct a stable amplifier. With regard to the reflecting properties of the test room, we agree that there would be an improvement in the absorption for a limited range of frequency if the cotton waste were supported some distance from the walls. The maximum effect would probably be obtained when a region of high velocity is included within the thickness of the waste. However, the scheme would hardly be practicable where the wavelength is large, e.g. 10 ft. or more. With regard to the distance of the source from the floor in the reflection tests in the test room, it is clearly impracticable to carry out tests with a motor half-way between the floor and the ceiling. The reflection tests were carried out with the source at a distance from the floor corresponding to the position of the centre line of the average motor, viz. 15 in.

In reply to Dr. Davis's remarks, we appreciate the references he has given, some of which we had not seen. With regard to the paper of Spooner and Foltz* published in March 1929, attention may be drawn to the fact that our No. 1 apparatus, embodying all the essential features of present practice, was in use in April 1927, and the present paper was accepted by the Institution in December 1928. The heterodyne method described by Dr. Davis would no doubt be of great value for certain work. We imagine that it is essentially a laboratory method. With regard to Steinberg's theoretical work on the assessment of total noise, we are interested to hear that these ideas are being abandoned. We have looked in vain for some comprehensive experimental confirmation of them. We admit that the loudness scale used by us may be neither strictly correct nor the final solution of the matter, but it has been of great service to us. It has in all cases indicated that component of noise in a machine which requires most attention. We shall be quite ready to change over to a more accurate loudness scale when one is evolved. Perhaps the National Physical Laboratory can assist in this direction. We are interested to hear that Dr. Davis has been experimenting with the reference tone and masking methods of instrumentally measuring total noise. A few experiments which we have carried out in measuring the noise of a motor, using reference tones of 500 and 1 500 cycles per sec., have given us the impression that the method is very promising. We much appreciate Dr. Davis's valuable contribution to the discussion.

Mr. Marris asks for the interpretation of the results given for a turbo-generator. If Section (13) of the paper be referred to, it will be seen that the paper covers methods of noise analysis and measurement only, and that such subjects as the interpretation of results and the methods which are effective in reducing noise are beyond the scope of the paper. We find it difficult to see any reason for the criticism that we have "concentrated on the lower frequencies." The apparatus is at present calibrated up to 5 500 cycles per sec., but if higher frequencies were present they would be detected. The highest frequency which so far has been encountered on motors is 3 300 cycles per sec. We regret that Mr. Marris is "not convinced by our arguments" regarding the use of the moving-coil microphone ; we can only say that we have found the instrument entirely adequate for our purpose. The variation of the response with frequency causes no inconvenience when a frequency analyser is used by means of which each component frequency is dealt with individually. The oscillograph method is confined to the very few cases where a frequency analyser cannot be used. The variation of response with frequency both in the microphone and in the analyser will certainly distort the oscillograph record but, even so, much useful information can be obtained. We wish to make it clear that we hold no brief for the moving-coil instrument—we have simply found that it serves our purpose exceedingly well. We shall be quite ready to use any other type when there is a clear advantage in doing so. It is obvious that the sensitivity of the condenser instrument is much less variable with frequency than that of the moving-coil instrument, but in looking through the various publications on the subject we have been unable to find any reference to whether the maker's calibrations by the thermophone have been corrected for the effect of the dimensions of the microphone when used in free space. If this correction has not been made, the sensitivity in free space will begin to rise at about 1 200 cycles per sec., increasing to double the uncorrected values at frequencies of about 4 600 and over. Mr. Aldridge * has drawn attention to this and to other sources of error which may arise if a microphone intended for use in free space is calibrated by the thermophone and used without subsequent correction. In his paper, the calibration curve obtained from the thermophone shows the usual very small drop of response with frequency. However, the true response curve for free space shows a variation of 2·2 to 1 between 500 and 1 800 cycles per sec., and that the true response at 1 800 cycles per sec. is 3·3 times the thermophone calibration. It is surprising that quantitative information on so fundamental a point has not been more readily available.

* W. West: "The Measurement of Sound Pressures on an Obstacle," *Journal I.E.E.*, 1929, vol. 67, p. 1137.

* *Journal of the American I.E.E.*, 1929, vol. 48, p. 199.

Dr. Hughes has already called attention to the day-to-day variations in the sensitivity of the condenser instrument, which are larger than any we have experienced with the moving-coil instrument. The absence of such variations is of great value, as it enables the effect of small changes made in the apparatus under test to be assessed. The condenser instrument and its associated apparatus are not, even in the most experienced hands, free from phase distortion. A curve given by Dr. Harvey Fletcher on page 28 of his book " Speech and Hearing " (O. van Nostrand Co., 1929) shows that the overall phase displacement of an oscillographic apparatus is nearly proportional to frequency and reaches a value of 80° at 4 500 cycles per sec. In calling attention to these points, we do not wish to belittle in any way the achievements of the condenser instrument, but we feel that criticism has been directed against our methods on the tacit assumption that the condenser microphone and everything connected with it is beyond criticism. In reference to the sensitivity of the moving-coil microphone, the fact that we are able to make measurements below the limit of audibility at all frequencies up to 800 cycles per sec. with a quite moderate amount of amplification is, we think, a sufficient answer. We have considered the added mass effect. For our particular conditions it is quite inappreciable.

We are very glad to have Mr. West's comments on the added baffle method of deducing the correction for the microphone dimensions. We think that the want of proportionality between the wavelength and baffle diameter may be due to our varying one dimension of the microphone, viz. the diameter, without varying the length. We think that this and other effects mentioned by Mr. West are covered by the continuous reduction, in small steps, of the baffle diameter until the diameter of the microphone alone is reached. The influence on the results of the conditions at large baffle diameters is very small. With regard to the detailed investigation of transient sounds, our apparatus would certainly require modification. An opportunity of going into this matter has not yet arisen, as the measurement of steady sounds has needed much more attention.

ELECTRO-PHYSICS.*

By D. Owen, B.A., D.Sc.

Fundamental Theory.

In the past four years the main objective of physical investigation has been the further elucidation of the structure of the atom. The Rutherford-Bohr conception presented a simple picture of the atom with its minute massive central nucleus, and its orbital electrons whose number (the atomic number) determines almost entirely the physical and chemical properties of an element. The idea of "stationary states," when the electron moves in its orbit without radiating energy, and of the jumps of the electron from one stationary state to another of lower energy, attended by the emission of definite bundles of monochromatic radiation called quanta, gave a remarkably simple interpretation of the laws of series in optical and X-ray spectra, and indicated quite plainly the necessity for some system of mechanics other than the classical or Newtonian mechanics in dealing with actions within the province of the atom. Much in the first quantum mechanics was puzzling, and many gaps remained to be filled in. Great progress has been made recently in supplying these requirements, and the wave mechanics, the work of L. de Broglie, Heisenberg, Schrödinger and others, is the outcome. Not that an entirely new basis of physical theory was demanded—the laws of the conservation of energy and momentum remain as essential as before. Rather does the wave mechanics serve to supplement the mechanics of massive bodies in treating of the fine structure of matter, just as undulatory optics replaces geometrical optics in dealing with interference and diffraction phenomena. The new views have received startling confirmation from the experiments on electron waves carried out by G. P. Thomson in Britain and by Davisson and Germer in America. In these we see moving electrons possessed of properties usually associated with waves, capable of being diffracted according to optical laws as well as deflected by electric and magnetic fields. These new phenomena seem to place us well on the way to the resolution of the paradox of recent years, namely, of radiation behaving at once as a compact quantum and as an expanding uniform wave-front. Probability methods have been applied with much success in the development of wave mechanics, in both the Bose-Einstein and the Fermi-Dirac statistics. The general theory of quantum mechanics appears indeed to be almost complete, the difficulty encountered in specific problems being mainly that of obtaining exact mathematical solutions. The root idea of the quantum remains, and it is necessary to accept the existence in natural phenomena of an essential discontinuity symbolized by Planck's constant. The reality of the quantum has been emphasized by two important recent discoveries, the Compton and the Raman effects.

On the side of magnetism a definite advance in theory has been made in the introduction of the conception of the spinning electron, put forward by Goudsmit and Uhlenbeck in 1926. This spin confers on the electron a permanent magnetic moment, in addition to the magnetic moment arising from its orbital motion in the atom. It adds another degree of complexity to the structure of the electron, making magnetism one of its fundamental properties. Perhaps we have in the forces of attraction thus introduced between its parts an indication of the mode in which an electron is able to retain its compactness in spite of the disruptive tendency of the electrostatic forces present within it. L. V. King has worked out a view of the spinning electron on classical lines; this will be welcome in so far as it permits a simple picture of the electron to be retained.

Our knowledge of the nucleus of the atom is steadily growing. The simplest line of advance is due to F. W. Aston, who has designed and constructed a new mass spectrograph capable of an accuracy of 1 in 10 000 in the estimation of the mass of the atom. By these measurements the isotopic constitution of the elements, and the fundamental character of the whole-number law of atomic mass, have been established. No atom in the whole range from hydrogen to mercury has a mass diverging from an integer by as much as 0·1. The interpretation of the slight divergences in terms of the doctrine of the equivalence of energy and mass is of the greatest importance for the light it promises to throw on the stability of the elements.

The theory of relativity still holds a fundamental place in physical theory. All doubts as to the validity of the Michelson-Morley experiment, on which the relativity principle was first based, appear to have been completely dispelled by the repetition of the experiment in 1928 by Michelson over a greatly increased light-path—as before with completely negative results. In view of the importance assigned in this theory to c, the velocity of light in free space, as constituting a universal constant, Michelson has also recently made and completed a new determination of this quantity, the result found being 299 796 ± 1 km per sec.

Magnetism.

The desirability has long been felt of investigating the effects of intense magnetic fields on the properties of bodies. It was realized that little help in producing extremely strong fields was to be gained by the use of ferromagnetic materials. The notion of utilizing the great fall in resistance of conductors with temperature has been worked out, only to be rejected on the score of cost. Prof. Cotton at Paris has now constructed his electromagnet, which is expected to provide fields up to 100 000 gauss. Dr. Kapitza at Cambridge has aimed at producing electric currents of an intensity sufficient to maintain for a short time a field approaching 1 million gauss. The story of his work constitutes an epic page in recent scientific research. In his first tentative experiments in 1924 he succeeded, with accumulators as the source of current, in producing fields of 40 000 gauss with which experiments on the bending of α-rays were carried out; next he investigated the Zeeman effect with fields of 100 000 gauss. By 1927 he had succeeded, by the use of the current obtained by short-circuiting the armature of a specially designed alternator, in reaching a field of 320 000 gauss. A considerable series of investigations has been carried out in fields of this value, and by the development of the full power of the machine fields up to 700 000 gauss should be attained.

---

* A review of progress. Reprints in pamphlet form, price 1s. each, can be obtained from the Secretary of the Institution.

A machine of 2 000-kW continuous rating was found to be necessary, and was constructed. Its weight is 13 tons, and a special laboratory has been built for it. By a special design of excitation windings a flat-topped current wave was obtained, so that the central part of the half cycle produced a steady current, and therefore a uniform field, in the central region of a small coil to which it was joined in series. The connection of this coil to the armature constitutes practically a short-circuit of the machine, the current for a field of 320 000 gauss within the coil rising to 72 000 amperes, and the power developed to 160 000 kW. To avoid heavy sparking the circuit is broken at the instant that the current passes through zero, the switching operation having therefore to be timed with an error not exceeding 0·0003 sec. In order to withstand the enormous stresses present in the experimental coil, this was surrounded with a bandage consisting of a ring of hardened and tempered steel. This steel ring had to sustain a total force over its periphery of 100 tons weight. One effect of the stresses is to increase the diameter of the coil, and to obviate breakage due to this a slipping contact was devised, with complete success. Towards the completion of this ambitious project help in design has been given by Prof. Miles Walker, H. T. Tizard and F. E. Smith. The undertaking has been financed throughout by the Department of Scientific and Industrial Research.

A brief account only can be given of the first results obtained with this plant. The effect of a magnetic field on the electrical conductivity of single crystals of bismuth was selected for first attention. Rods of bismuth 2 cm^3 in volume were required. These could not be turned from a large block of crystal owing to the destructive effect of such treatment on the homogeneity of the specimen. The problem of growing large crystals in the form of rods was faced and solved, and a thorough study was made of the effect of orientation of the crystal with respect to the direction of the current through it and to the direction of the applied magnetic field. A method was discovered of growing crystals having any required angle between the axis of the rod and the cleavage plane of the crystal. The test current through the crystal was about 3 amperes. This, as well as the fall of potential between two points on the rod, and the current in the surrounding magnetizing coil, was measured by a 3-circuit oscillograph. The electrodynamic force on the rod is not large, but the forces arising from the difference in the magnetic susceptibilities of bismuth and liquid oxygen in the low-temperature experiments amounted to from 1 to 5 kg, and the rod had to be tightly secured in position. The first effect of the magnetic field is to produce a temporary back e.m.f. in the rod (an effect previously observed by Seidler). Eliminating the effect of this in reducing his results, Kapitza finds that the effect of a magnetic field H on the electrical resistance R may be analysed into two parts: (1) in which $\Delta R/R_0 = \alpha H^2$, holding in fields up to 50 000 or 100 000 gauss, and (2) in which $\Delta R/R_0 = \beta H$, for all higher fields. The constant α depends on the orientation of the crystal; the constant β is the same for all orientations. The effect occurs only when H is transverse to the direction of the current in the crystal, there being no effect in longitudinal fields. The change of resistance increases very rapidly, according to an inverse fourth-power or fifth-power law, with fall of temperature. Experiments have been made on 35 other metals, which were obtained in a very pure state (at least 99·9 per cent), the general result found being that the same laws apply to all, with the exception of the ferromagnetic metals, which are clearly anomalous and are to be the subject of a further special study. The magnitude of the effect in the case of bismuth, antimony and arsenic is enormous. In the maximum field of 320 000 gauss, bismuth increases its resistance 50 times at ordinary temperature, and 1 360 times at the temperature of liquid air. The factors of increase for antimony and arsenic in the maximum field at the temperature of liquid air are 40 and 29 respectively; and the corresponding increases for certain metals are as follows: magnesium 300 per cent, zinc 100 per cent and copper 40 per cent. For iron the change under the same conditions is 5 per cent, and for nickel 4 per cent.

The correlation of the above results with theory is a matter of much importance. A treatment of the change of resistance of conductors under the influence of a magnetic field was first given in 1900 by Sir J. J. Thomson, and quite recently Sommerfeld has dealt with the question. But the amount of the change predicted on these theories is almost negligibly small compared with the results observed. Kapitza makes some suggestions based on the new data he has obtained. From the fact that the linear part of the curve connecting R and H is independent of orientation and of the degree of perfection of crystalline form of the material, he infers that the effect is an atomic phenomenon. He divides the total resistance of a metal into two parts: (1) an " ideal " resistance which falls to immeasurably small values with fall of temperature, and (2) an " additional " resistance dependent on the physical state. He thinks that by careful crystallization and by eliminating internal mechanical strain the condition of supra-conductivity may be produced in all metals. Non-metals and semi-conductors appear to fall into a separate category and to need different considerations.

Gyro-magnetic Effect.—According to a simple form of classical theory the magnetization of a body is due to electrons in rotation within the atoms. The rotating electron will possess angular momentum and magnetic moment, the ratio of these, called the gyro-magnetic ratio, being constant and equal to $2m/e$, where e is the charge and m the mass of the electron. On this view an iron rod spun about its axis should become magnetized; and conversely, as O. W. Richardson pointed out in 1908, a rod in the act of being magnetized should experience a rotational mechanical reaction. Both of these effects have been observed; but in each case the value of the gyromagnetic ratio deduced from the measurements turns out to be just half of that expected. The recent experiments of Sucksmith and Bates at Bristol prove this, as regards the converse effect, in the cases of iron, nickel, cobalt, the Heusler alloys and magnetite. Richardson has thus been led to the view, supported also very strongly by spectroscopic evidence, that the nucleus of the atom has also a quantized spin, possessing an angular momentum one-half the total value of that of the orbital electrons in the atom, but opposite in sign.

Perminvar.—To the list of iron alloys of high permeability, such as permalloy and mumetal, which have already proved their immense value in telephony, has now been added by Arnold and Elmen an alloy of iron, nickel and cobalt which has the interesting property of possessing, for fields below 1·7 gauss, a permeability of nearly 500, constant within 1 per cent over this range. To this material the name "perminvar" has appropriately been given. Within the same range of field the hysteresis loss is vanishingly small, being only 1/1 000th of that of permalloy, itself very small, as is well known, compared with the hysteresis loss in pure iron.

Solar Magnetism.—The sun's magnetism was detected 21 years ago by Hale. It is now known that the magnetic axis is inclined some 4° to the axis of rotation, and that the polarity is related to the direction of rotation exactly as in the case of the earth, so that the north magnetic pole is near the top of the sun as viewed from the earth's northern hemisphere. The intensity of the field at the poles is 50 gauss (the field at the earth's poles is 0·66 gauss). Superimposed on the general field are local fields, associated with sunspots, where the intensity may be as high as 3 000 gauss.

ELECTRON WAVES, AND THE WAVE MECHANICS.

The 25-year old problem of the reconciliation of the wave and the emission theories of electromagnetic radiation has now been attacked both theoretically and experimentally with startling success. In 1924 Louis de Broglie, combining the relativity and quantum theories, showed mathematically that a particle of mass m, moving with velocity v, is accompanied by a phase wave of frequency ν travelling with a velocity c^2/v. Associated with it is a wave group advancing with the same speed as the particle and (unlike the phase wave) carrying with it energy and momentum, the wavelength being equal to $h/(mv)$, that is, to Planck's constant divided by the momentum of the particle. Applying the theory to the case of the α-particle, we find it carries with it in its motion a group of waves of wavelength about $0{\cdot}5 \times 10^{-4}$ Å (Ångstrom units), equal, that is, to that of very short γ-rays. A hydrogen molecule moving at the mean translational speed corresponding to ordinary temperature carries to-and-fro a group of waves of wavelength 1·1 Å, which is that of ordinary X-rays. Greatest practical interest, however, attaches to the wave system accompanying a moving electron or cathode ray. If by the relation $eV = \frac{1}{2}mv^2$ we replace the speed v by the voltage V, falling through which the electron acquires its kinetic energy, we may write the de Broglie formula in the form $\lambda = 12{\cdot}24/\sqrt{V}$. Contrasting this with the formula for the limiting wavelength of X-rays, namely, $\lambda_x = 12\,350/V$, we see that moderately hard X-rays, generated by 10 000-volt electrons, are of about the same wavelength as the de Broglie waves carried by electrons which have fallen through 100 volts. Now if cathode rays or moving electrons are indeed associated with waves, diffraction effects should be observed when the electrons are reflected by a grating, or when they are transmitted through a very thin crystalline film. These phenomena have been brilliantly observed and measured, the former by Davisson and Germer, the latter by G. P. Thomson. Davisson and Germer allowed a narrow sheaf of cathode rays to fall at a definite angle of incidence upon a single crystal of nickel, and observed that the reflected rays pass through a series of maxima of intensity as the angle of reflection changes. They show, in fact, phenomena of the same character as the diffraction fringes exhibited by light when reflected from a ruled grating.

G. P. Thomson, using cathode rays of about 30 000 electron-volts, allowed a fine pencil of the rays to fall upon films of various metals. Owing to the strong absorption which they cause, the films have to be very thin, and Thomson has succeeded in producing spluttered films no thicker than 10^{-6} cm, free from holes and almost quite transparent to ordinary light. Such films contain crystals in all orientations, and it was expected that diffraction rings would be produced on a photographic plate on the other side of the film, similar in type to those produced by X-rays in the Hull-Debye-Scherrer method of analysis. These anticipations were fully realized, and from the measurement of the diameters of the successive rings the wavelength could be determined and compared with the value $h/(mv)$ indicated by de Broglie's theory. The agreement of theory and observation is complete. These waves differ from X-rays of the same wavelength by being associated with electrons, and therefore capable of being deflected by electric and magnetic fields.

Rupp has observed the diffraction of cathode rays by a ruled grating (of metal to avoid static charges), and has thus succeeded in measuring the wavelength of the electron waves in terms of the grating space.

We are thus in presence of a new phenomenon, in the possession by a moving electron of a duality of wave and corpuscular properties, exactly parallel with the peculiarity shown by light in possessing at the same time the properties of quanta and of a continuous wave-front. The development of the wave mechanics is due chiefly to Heisenberg and Schrödinger. It has the advantage over the first quantum mechanics of Bohr of disclosing the presence of waves associated with the electron as it moves in its atomic orbit, of a frequency identical with that of the radiation emitted in one of its transitions. By combining the formula $\lambda = h/(mv)$ with the Bohr expression $nh/(2\pi a)$ for the momentum in a circular orbit of radius a, it is seen that $\lambda = 2\pi a/n$, so that the number of waves in a complete electronic orbit is an integer, one for the innermost orbit, two for the next, and so on. The wave mechanics has also been applied with great success by O. W. Richardson and others to the interpretation of band spectra, now known to be phenomena of the molecule as line spectra are phenomena of the atom.

X-RAYS.

For many years the range of X-rays has been comprised between about 10 Å and 0·1 Å. It has by now been extended both on the long-wave and the short-wave sides. Using the formula $\lambda = 12\,350/V$ for the shortest wavelength generated by a voltage V, it is seen that to extend the range on the long-wave side a fall of potential of less than 1 000 volts across the X-ray tube must be used. To avoid space-charge effects at such low voltages the electrodes must be placed close together. The absorption of soft X-rays by a metal is very great, and the rays are consequently generated only in a very thin layer of the surface of the anti-cathode. This layer, for a given metal, may be obtained by using that metal as the material of the cathode filament, or by placing it on the hot filament which is composed of a metal of much higher melting point. Volatilization occurs, followed by condensation on the anti-cathode, which may be of some neutral metal such as iron. Hot filaments of large diameter have to be used to permit of sufficient current through the tube to provide the intensity of X-rays required.

At such large values of λ the Bragg spectrometer method fails, since, according to the formula $n\lambda = 2d \sin\theta$, even with a spacing constant as high as 21 Å (using cane-sugar) the highest value of λ measurable must fall below 42 Å. Now A. H. Compton in 1925 suggested a new method of producing X-ray spectra by reflecting them from an ordinary optical diffraction grating at very nearly grazing incidence. The dispersive power of a grating is greatly improved by using small glancing angles; furthermore, owing to the fact that the refractive index of X-rays is less than unity, there is a critical glancing angle below which the rays are totally reflected. By working at angles below this critical value, which at $\lambda = 1{\cdot}6$ Å is under 25′ of arc, it was found possible to obtain sufficient intensity in the reflected beam to affect a photographic plate with comparatively short exposures. In 1927 Thibaud perfected the technique of the method and succeeded in obtaining very sharply defined photographs of characteristic X-ray spectra down to long wavelengths. He finds that glass gratings are preferable to metal, and for the long waves uses a grating of either 11 000 or 22 000 lines per cm, of the type produced at the National Physical Laboratory. He has obtained photographs of the K-series of certain light elements (O, N, C, B), the N-series of some heavy elements (Pt, W, Ta, Au), and the O-series of thorium, this last including a line at 68·1 Å. The method applies also in the ultra-violet and the extreme ultra-violet parts of the spectrum, and Thibaud, using glass gratings of 2 000 lines per cm, has succeeded in registering the whole spectrum from 6 000 Å (in the visible region) to 140 Å (the longest wavelength of the Millikan region) on the same photographic plate. Hoag, using a concave grating, has also succeeded in obtaining beautifully defined spectra of the elements C, O and N between 200 and 1 650 Å.

The use of the ruled grating in the province of X-rays has an added importance as promising a new basis for the accurate determination of the electronic charge e. The wavelength of a spectral line as determined by the grating depends only upon the number of lines in the grating and the angular measurements. The wavelength value determined by using the crystal depends on the spacing between the crystal planes, the estimation of which involves the knowledge of e. Usually Millikan's value $4{\cdot}774 \times 10^{-10}$ electrostatic units is assumed, and this value has hitherto been regarded as probably correct to 1 part in 1 000. But if the absolute wavelength of some spectral line be found by the ruled grating, it becomes possible from the data of measurement with the same spectral line by the crystal method to calculate the crystal spacing, and to proceed thence to a determination of e. Already Bäcklin, working in Siegbahn's laboratory, has arrived at a value $e = 4{\cdot}793 \times 10^{-10}$ electrostatic units, estimated correct to 3 parts in 1 000. Greater precision of measurement, and an assured foundation for the formulæ used in the calculations, have, however, yet to be acquired to permit of the possibilities of this method being adequately realized. The position is of interest also in relation to a recent mathematical theory of Eddington's, based on considerations of wave mechanics which would require the quantity $hc/(2\pi e^2)$ to be an exact integer, namely 136, in place of the value 137·1 found on substituting the hitherto usually accepted values for e, h and c.*

On the side of short wavelengths Thibaud and Frilley have succeeded in getting down to a wavelength of 0·016 Å. Coolidge, by using three discharge tubes in series, has produced cathode rays and X-rays corresponding to a total fall of potential of 900 000 volts, in stages of 300 000 volts each. The limit of voltage per stage is set by the emergence of the "cold electron" discharge (dealt with at further length in this Report), which sets in at voltages of about 300 000. The fine jets of electrons thereby produced impinge on the glass walls of the tube, causing local heating leading to puncture; whilst if they happen to fall on the anode the local heating sets up an arc discharge. The results obtained by Coolidge appear to be very striking. Intense luminous effects are produced if the cathode rays are allowed to emerge through a thin metallic window, while the X-rays are said to be of such intensity as to produce luminosity on a fluorescent screen held 100 ft. away. Their frequency falls within the range of γ-rays, though far short of that of the most penetrating γ-rays, which possess a quantum energy of 3 to 4 million electron-volts.

Compton Effect.—In 1923 A. H. Compton proposed a quantum theory of the scattering of X-rays by electrons. The classical theory requires scattering without change of wavelength, whereas the theory of Compton involves an increase of wavelength as shown by the formula $\Delta\lambda = (1 - \cos\theta)h/(mc) = 0{\cdot}0242(1 - \cos\theta)$ Å, where θ represents the angle of scattering. The increase of wavelength postulated is independent of the initial wavelength. It varies from zero up to a maximum of 0·048 Å according to the value of θ, the maximum change occurring when the scattered ray travels in the reverse direction to the incident ray. The existence of the new effect is now well established. Both types of scattering occur, but within the visible spectrum the intensity of the Compton scattering is inappreciable. At X-ray frequencies, however, the Compton effect is quite marked, and for short γ-rays becomes of preponderating importance.

---

* Eddington has recently (*Nature*, 1929, vol. 124, p. 840) given reasons for revising his conclusion in favour of the integer 137.

The effect constitues a striking testimony to the reality of quanta of radiation. If the frequency of the incident beam is ν, the quantum of energy is $h\nu$, its momentum is $h\nu/c$, and its mass $h\nu/c^2$. When the quantum impinges on a free electron it shares its energy and momentum with the electron, in conformity with the laws of conservation of energy and momentum. At low frequencies the mass of the quantum is small compared with the mass of the electron, and the degradation of frequency is of little consequence. At an incident wavelength of 0·048 Å the frequency of the scattered quantum for direct incidence is exactly halved, and the energy is shared equally between the scattered quantum and the electron. At much higher frequencies the mass of the quantum far exceeds that of the electron at rest, and most of its energy is transferred to the electron.

The Compton effect has an interesting application to the highly penetrating or "cosmic" rays discovered by Millikan and Kolhörster. Sir James Jeans has suggested that these rays owe their origin to the union of a proton with an electron, with mutual annihilation of charge and attended by the production of a quantum of radiation of the same energy, namely, 920 000 electron-volts. The collision of such quanta with electrons would raise the speed of the electrons to within a few parts in a million of that of light, and so confer on them a mass almost equal to that of the proton at rest. The wavelength of the cosmic rays can only be inferred from their measured absorption coefficient. The results of Millikan and Cameron inserted in the Klein-Mishina absorption formula, which is based on wave mechanical principles, lead to a wavelength agreeing very closely with Jeans's hypothesis.

Electric Conduction in Metals.

In 1928 Sommerfeld applied wave mechanics and the Fermi-Dirac statistics to the doctrine of free electrons in metals, with the result of eliminating many of the discrepancies between the early theory and observation. According to Sommerfeld's theory there is one free electron per atom of a metal, and the contribution of these to the specific heat is less than 1 per cent of that postulated on the old theory, so that the difficulty in regard to the specific-heat value disappears. As in the older theory, the ratio of the thermal and electrical conductivities comes out proportional to the absolute temperature. In regard to thermo-electric phenomena, the experimental data are in good accord with the Sommerfeld theory. However, as already pointed out, the enormous effect of magnetic fields on the resistance of metals is too great to be accounted for on either the new or the old theory. Kapitza's suggestions, and his conclusions in regard to supra-conductivity, are stated above. It may be noted that tantalum and thorium have now been added to the list of supra-conductors. Like those previously discovered, these metals are of high atomic number.

The passage of electricity through solids of very low conductivity has been studied by Joffé, Pohl and Gudden, and others. An immediate simplification, from the point of view of theory, is evidently effected by working with single crystals, owing to our present fairly complete knowledge of the structure of the crystalline lattice. The brothers Curie were the first to make measurements of the electrical conductivity of crystals, and Joffé has continued and perfected their methods. When a steady electromotive force is applied to a crystal, say rock salt or quartz, polarization phenomena manifest themselves and the current slowly falls with time. Joffé has shown how to measure this polarization e.m.f., and on allowing for it he finds that the conduction obeys Ohm's law, so that the crystal has a true conductivity. With different specimens of the same substance, however, he found widely divergent values for the conductivity. This he has traced to the presence of impurities, and by repeated re-crystallization he has been able to show that this variation disappears. With crystals of the cubic system, like $NaNO_3$, NaCl, etc., he found the conductivity σ to be independent of the orientation of the crystal. In crystals belonging to other systems the conductivity varies greatly in different directions, far more so than the thermal conductivity. In quartz, for example, σ is many thousands of times greater along the optic axis than perpendicular to it, whilst the thermal conductivities differ only by 20 to 80 per cent.

The formula $\sigma = \sigma_0 e^{-a/T}$ represents the relation between conductivity and temperature, the constant a being practically the same for all heteropolar crystals, namely, between $1{\cdot}0 \times 10^{-4}$ and $1{\cdot}15 \times 10^{-4}$. The temperature coefficient of electrical conductivity of pure dielectric crystals is thus very high, a rise of 1 deg. C. causing an increase of from 10 to 20 per cent. This is in sharp contrast with the dielectric constant, the value of which is almost independent of the temperature.

The mechanism of conduction in crystals appears to be of two types. Normally it is of the electrolytic type; but, if the crystal is illuminated, electrons are liberated in the interior and act as carriers of the current. The first type involves a movement of ions, matter being transferred in accordance with Faraday's laws and deposited at the electrodes. The conduction differs, however, from that in liquid electrolytes in that practically only one kind of ion is mobile. In most of the halides the positive is the mobile ion: for example, Na + in the case of rock salt. In general, the conductivities in question are extremely small, the value for ammonium alum, for instance, being given as 20×10^{-16} ohm^{-1} cm^{-1}, and the number of free ions per cubic centimetre is very small at temperatures far removed from the melting point. For quartz the number of free ions is about 1 per 10^{13} of those present in the lattice, and the calculated mobility is 5×10^{-7} cm/sec. for 1 volt/cm. As conduction proceeds and fresh ions are removed from the lattice the crystal breaks down, and holes have sometimes been observed to develop.

If, however, the transparent crystal is illuminated, electronic conduction occurs. The action of the light appears to be enormously increased by previous irradiation with X-rays, although the direct effect of these rays in increasing the conductivity appears to be but small. This "activation" by X-rays is attributed to the production of neutral atoms or groups of atoms in the lattice, and at the same time the liberation of electrons: it being easier to set these free in the interior than to expel them through the free surface of the material. At liquid-air temperatures the ionic or electrolytic conduction becomes vanishingly small, whilst the electronic conduction persists and can therefore under these conditions be more easily studied. Pohl and Gudden have worked with diamond, zinc sulphide and selenium, which belong to a class of substances in which no previous activation with X-rays is necessary. In these cases, in contrast with rock salt for instance, a complete saturation current can be observed, and from the value of this the number of electrons per cubic centimetre can be deduced. Their observations lead to the conclusion that one free electron is produced within the crystal for each quantum of light absorbed. This work is of great interest in its bearing on the selenium cell.

ELECTRIC CONDUCTION AT THE SURFACE OF A SOLID.

Lee du Bridge has made measurements of the photo-electric and the thermionic work-functions of platinum, taking the utmost care to eliminate that serious source of error in all such work, namely, the presence of gas films at the surface. As "outgassing" proceeded, the photo-electric threshold was observed to shift steadily towards the shorter wavelengths, reaching after prolonged treatment in the highest attainable vacua the limiting value 1926 Å, equivalent to 6·30.electron-volts. Similarly the thermionic work-function, that is, the coefficient w in the equation $i = AT^2e^{-w/(RT)}$, was found to increase under a like treatment and to reach the limit of 6·35 electron-volts (± 1 per cent). The coefficient A reaches a corresponding limit of 14 000. This demonstration appears to be a final confirmation of the theoretical conclusion, reached by O. W. Richardson some years ago, that these work functions are identical. As the form of the thermionic equation shows, the value of the thermionic emission at any given temperature is enormously sensitive to changes in w or $\phi_0(w = e\phi_0)$. Thus in the case of tungsten, coating the surface with oxygen raises ϕ_0 from 4·5 to 9·2 volts; whilst coating it with thoria lowers it to 2·68 volts, and with cæsium to only 0·715 volt. The application to the properties of the dull-emitter filament is obvious.

The phenomenon of the extraction of electrons from cold metals under intense electric fields has received careful experimental investigation at the hands of R. A. Millikan in America and of B. S. Gossling in England. These currents, obtained in the highest vacua, were apparently first observed by Lilienfeld in 1921 in X-ray tubes, and have been variously designated as auto-electronic currents, or field currents, or under the name "aeona effect." Much earlier Earhart and others, working with minute spark-gaps in gases, claimed to have observed sparks at potentials below the minimum sparking potential of the gas. The values of electric field reached in their experiments were at least as high as those used in the experiments now to be described, but an uncertainty remained as to whether actual contact between the electrodes occurred owing to the electrostatic pull between them. Both Millikan and Gossling removed all doubt on this score by working with distances of the order of 1 cm between the electrodes. Using a fine wire along the axis of a cylindrical sheet of metal an intense field can be obtained at the surface of the wire by the use of quite moderate voltages. Thus with a tungsten wire of diameter 0·0012 cm along the axis of a copper cylinder of diameter 1·62 cm a field of over 1 million volts/cm is present with 4 800 volts between them.

The initial gradient at which a detectable current begins to flow is about 500 000 volts/cm. The current increases rapidly with the field F according to the exponential law $i = Ce^{-b/F}$, where C and b are constants, and currents up to several milliamperes may be observed. The discharge is not uniform, but usually occurs from a few points or only one point of the cathode, narrow pencils of current shooting out and producing corresponding hot points where they impinge on the anode. The strength of current is independent of the temperature of the metal up to about 600° C. At higher temperatures the usual saturation thermionic current becomes augmented in such intense electric fields, but this is an effect to be distinguished from the auto-electronic current when cold conductors are used.

Schottky has proposed a theory of the effect—as also of the effect of intense fields on thermionic emission—according to which the external field reduces the work function. The electric field opposing the escape of an electron may be regarded as arising from an attraction between the electron (when already outside the geometrical boundary of the metal) and its electrical image in the surface. Assuming, for example, that the electron will get clear if it is 10^{-8} cm outside the surface, a simple calculation shows that the work function is 3·6 electron-volts. To do this amount of work on the electron a uniform electric field of $3{\cdot}6 \times 10^8$ volts/cm would be required. This is, however, of the order of 100 times the field at which currents may be observed, assuming that the field is perfectly uniform. The existence of sharp points, or possibly (as Richardson suggests) the presence of local weak spots on the surface, may account for the difference.

It is the existence of this effect which explains the necessity of placing several cathode-ray or X-ray tubes in cascade when high voltages of a million or over are to be applied.

OTHER LINES OF ADVANCE.

In 1928 Sir C. V. Raman announced the discovery of a new effect when radiation is scattered by a transparent body. As in the case of the Compton effect, we have to do with a change of wavelength in the returning radiation. But whilst in the Compton effect there is an increase of wavelength varying in extent from zero to a fixed maximum independent of the incident radiation, in the effect discovered by Raman the incident radiation suffers definite and sharp changes of frequency which are determined by certain frequencies characteristic of the irradiated material. These changes of frequency are, in fact, found to be identical with the various rotational or vibrational frequencies of the molecule. Many of these characteristic vibrations, which are of comparatively low frequency, were already well known from the work of Rubens on residual rays, and have been the subject of recent investigation by Sir Robert Robertson and others in the infra-red spectrum. The Raman effect manifests the existence of these, and of many other lines previously unobserved. In the case of quartz, for instance, characteristic vibrations corresponding to lines at 118, 94, 78, 48·5, 37·4 and 21·5 μ have been discovered, all save the last of these being new. If N denotes the incident frequency, and n a frequency characteristic of the molecule, then lines of the frequencies $N \pm n$ will be found in the scattered radiation. It is of great interest that the lines occur in pairs, one being of enhanced frequency, though of much feebler intensity than the line of lowered frequency. The occurrence of lines of enhanced frequency is not in itself a new phenomenon. According to Stokes's law the light emitted by fluorescent bodies is lower in frequency than the exciting light; but it is now known that this law is by no means general. The presence of the lines in pairs, and the simplicity of the frequency relations, are facts readily interpreted on the quantum theory, and constitute a striking evidence of the reality of quanta. The effect promises to be of the highest importance in the elucidation of molecular structure.

A solution has at last been found to the question of the origin of the green auroral line 5 577·35 Å, which has been shown by McLennan to be emitted by atomic oxygen. Lord Rayleigh has observed that this ray may be seen not only in auroral regions, but also, though very faintly, over the whole of the night sky. The auroral spectrum also contains bands due to nitrogen, but the general illumination shows only the one green line, on a faint continuous background. The phenomenon is of interest in regard to the question of ionization within the Heaviside layer.

Debye has recently published in book form an account of his work on the influence of polar molecules, or dipoles, on dielectric constant and electrical conductivity. The presence of dipoles affects the rate of variation of these properties with temperature and with frequency. The values of the electric moment of such molecules can be determined by several methods, and their values have been tabulated for a considerable number of liquids.

Many investigations continue to be carried out on piezo-electric crystals. To name only a few, Dye has published an important theoretical and experimental investigation of the fundamental piezo-electric properties of quartz, and has later been engaged on a detailed study of the complex of vibrations present in the excited crystal. Pierce and others have applied the effect to the determination of the velocity and the properties of sound waves at supersonic frequencies. Pierce and Vincent have also investigated the production of high-frequency oscillatory currents by use of the magnetostriction effect in nichrome rods. Frequencies as high as ½ million per sec. may thus be attained, and it will be of interest to observe whether oscillators of this type prove of service in stabilizing radio frequencies. On the side of the relation between piezo-electric quality and crystal structure a valuable contribution has been made in papers by Sir William Bragg and R. E. Gibbs. Ordinary or "low" quartz changes its crystalline form at 575° C., passing into "high" quartz, the structure of which has been determined completely by X-ray analysis. The slight difference in structure due to the passage from the first form to the second, small as it is, is attended by a complete loss of piezo-electric properties. From the slight degree of asymmetry possessed by low quartz, Gibbs has calculated a value for the piezo-electric constant which comes out of the same order as the observed value.

A concluding reference will be made to the passing of H. A. Lorentz, the great mathematical physicist. He showed with eminent success how to combine Maxwell's theory with the later theory of electrons, and made valuable contributions to most branches of electrical theory during the past 50 years. He was also a great expositor, and the charm of his presence at scientific assemblies will be gratefully remembered by all who enjoyed the privilege of hearing him.

ELECTRICAL PLANT AND MACHINERY, INCLUDING MARINE APPLICATIONS.*

By A. R. EVEREST, Member.

TABLE OF CONTENTS.

(1) Generators and motors.
  (a) Direct-current machines.
  (b) Alternating-current machines.
  (c) Starting and control gear.
(2) Power transformers.
(3) Convertors and rectifiers.
  (a) Rotary convertors.
  (b) Motor convertors.
  (c) Mercury-arc rectifiers.
  (d) High-vacuum type thermionic rectifiers.
  (e) Hot-cathode mercury-vapour rectifiers.
  (f) Copper-oxide dry rectifiers.
(4) Power-factor correctors.
(5) Marine applications of electricity.
(6) Accumulators.
  (a) Lead-acid batteries.
  (b) Iron-nickel-alkali batteries.

(1) GENERATORS AND MOTORS.

(a) DIRECT-CURRENT MACHINES.

Much advance has recently been made both in the standardization of manufacture and in the scope of application.

Constructional.—Dealing first with constructional developments, the main feature to be noted is the extended substitution of "built-up steel" structures for castings. Beginning with the simpler forms, such as baseplates, the development has extended to cover complete magnet-frames with feet, end-shields, pedestals and other details. Elaborate wooden patterns, with the accompanying delays and costs, are eliminated, the material is more homogeneous, stocks can be reduced and cheapened, and production is accelerated. The welded joints are found to compare well, as regards strength, with the rest of the structure.

The use of ball and roller bearings is now very general on small sizes, while on larger sizes (above $3\frac{1}{2}$ in. diameter) their adoption is extending and the employment of roller bearings on machines for heavy duty, such as crane and traction work, has proved successful.

The several alternative types of enclosures of machines are being reduced and simplified; louvred covers for drip-proofing are becoming more general, while for totally enclosed motors two methods in particular are being employed to an increasing extent, both in England and on the Continent. The first and simpler, though less effective, method is to propel (by means of an external fan) and guide cool air over the outer surface of the frame (whether smooth or ribbed); while the second method consists in utilizing an internal fan for circulating the hot air through cooling tubes, an external fan providing cooling air on the outside of these tubes.

Electrical Design.—Electrical design may almost be said to be standardized on small and medium-size motors; but for large machines, with difficult commutating properties, special compensating windings and tapered air-gaps are employed, in addition to commutating poles, to improve the commutation. These developments, together with improvements in the mechanical design, have enabled high-power high-speed motors to be built for blowers, ventilators and other similar purposes.

The modern increased demand for machines in which the stable range of voltage or speed is wider than that hitherto provided has been met by the more general application of a long-known principle, viz. the introduction of points of high saturation into the magnetic circuits.

Applications.—The application of electrical energy to industrial mechanism is practically unlimited in its scope, and there are but few branches to which the electric motor has not been adapted. For general machine-tool purposes great headway in the use of electrical drive has been made, as indicated in both the British Industries Fair and the Leipzig Fair during recent years; but great diversity in practice is still to be found as regards the building in or attachment of the electrical unit to the machine-tool proper. In many cases the driving end-shield of the motor is provided with a bracket for bolting to the tool; in other instances the motor frame is furnished with a flange for this purpose, while in still other cases the motor is built into the tool housing.

The development and adoption of ball and roller bearings have enabled much higher speeds to be attained, thus permitting direct electric drive for such purposes as wood-working machinery running at 6 000 r.p.m. or higher speeds.

For the driving of winches and hoists, and the operation of navvies, dredgers, excavators, and similar duties, the Ward-Leonard system has been employed for many years. This system is based on the control of each motor or group of motors by a separate generator; variations in speed are obtained by variations in the generator voltage, both motor and generator being excited from a separate source.

It is, however, in some cases desirable to adopt a system possessing torque characteristics similar to those of a steam-driven set. These can be very closely obtained by the adoption of the scheme known as the "constant current" system, and considerable attention has been paid to this during the last few years. In this scheme the windings on the generator are so proportioned as to produce a characteristic giving practically constant current output over a large range of voltage. A number of motors can be driven by one generator; these are connected in series, their fields being separately excited; the desired variations in torque and speed are produced by varying the field excitation. If the torque exerted by any one motor varies owing to alteration in the mechanical loading, the resultant adjustment of current and counter-e.m.f. is immediately accompanied by a rapid compensating change in the generator voltage; it is, therefore, clear that, with any given excitation, the torque of the motor will remain constant over a wide range of impressed voltage. Any tendency of the motors to race when load is thrown off, due to an excessive rise of impressed voltage, is counteracted by a suitably arranged automatic reduction of the field strength. The motor characteristics can be varied considerably, by field adjustments, to produce accelerating and braking torques as required.

---

* A review of progress. Reprints in pamphlet form, price 1s. each, can be obtained from the Secretary of the Institution.

In electric railway service, train-lighting sets operating without the use of batteries have been developed with characteristics such that even with a considerable variation in the supply voltage (amounting to as much as a drop of 50 per cent) the alteration in the secondary voltage is maintained within satisfactorily close limits.

Another branch of growing importance is the electrical equipment of public laundries, the electric drive being eminently suited to the great diversity of types of machines in this class of work, e.g., washing and drying machines requiring frequent reversals, with, in certain cases, dynamic braking, and "inching"; ironing machines needing considerable speed variation; extractors requiring very high accelerating but small running torque; marking machines and belt conveyors; all of which apparatus generally requires to be capable of running in a steamy atmosphere.

The talking-film development in the cinema industry has brought in its train a demand for small rotary convertors or motor-generator sets; the generators of the latter are of a fixed output and voltage, while the motors are varied to suit the changing local supply conditions.

High-Voltage D.C. Generators.—With the development and rapid spread of wireless transmission has come a demand for high-tension direct-current generators for the purpose of energizing the anodes of transmitting valves. At first, various voltages were adopted as considered desirable in each individual case, but the present tendency seems to indicate 12 000 volts as being the most suitable value.

The actual type of design has not yet settled down to any definite standard, as some firms advocate the 2-pole design, giving a comparatively low voltage per commutator bar, while others prefer the multi-polar type, in spite of the resultant higher voltage per bar, in order to avoid the difficulties of insulation met with in bi-polar armature end-windings using conductors of small section. Some, again, build the field structure of the normal salient-pole type, while others resort to a completely compensating distributing winding. The commutating-pole winding is generally arranged on both sides of the armature to act as a protection against voltage surges.

(*b*) Alternating-Current Machines.

Induction Motors.—In the many applications associated with the modern rapid development of electric power there has been a marked tendency to prefer the squirrel-cage type of induction motor on account of its simplicity, ruggedness and low cost; but for services demanding high starting torque this type of motor has been generally inadequate, and for such purposes it has been necessary to employ the slip-ring motor, notwithstanding its increased complication and inherent lower efficiency and power factor. Recent improvements in design have resulted in the evolution of motors of the squirrel-cage type capable of completely replacing the slip-ring motor.

For applications in which the duty comprises chiefly starting and accelerating, as in many cases of lift work, the squirrel-cage motor with high-resistance rotor in conjunction with a special speed-change stator winding has proved successful. The ordinary change-pole stator winding is limited to a speed ratio of 2 : 1, but by providing two separate change-pole stator windings the speed is successively stepped up in the ratios 2 : 1, 3 : 1, 4 : 1 and 6 : 1.

For more general applications, providing for continuous running at a definite speed in addition to high starting torque, various means for producing the necessary high rotor resistance at start have been tried, and of these the double-squirrelcage rotor, originally proposed by Boucherot 25 years ago, has recently been brought to full development.

In this type of motor, the rotor has two squirrel-cage windings one above the other; the upper squirrel-cage is of high resistance, while the lower squirrel-cage is of low resistance, but on account of the position of the bars in the slots it has high reactance. In consequence, at starting, when the rotor frequency is the same as that of the stator, the lower winding, on account of its high reactance, takes little current, while the upper squirrel-cage is active and the motor starts with the high torque and low starting-current characteristics of a high-resistance rotor. When run up to speed, the low slip-frequency allows the lower squirrel-cage to become effective, and its lower resistance largely determines the running characteristics.

A motor of this type, intended for crane and elevator drive, will give gradually increasing torque from full speed to standstill, with low starting current. The efficiency of the double-squirrelcage rotor is generally but slightly less than that of a motor with the ordinary single-squirrelcage rotor. The double-cage construction has the disadvantage of slightly decreasing the power factor, which, however, is still superior to that of the slip-ring motor.

Squirrel-cage construction favours the elimination of the objectionable humming noise usually associated with slip-ring motors, and designers have given this point special attention.

If fine speed-adjustment under running conditions is desired it is readily obtained by resistance control in series with the stator windings.

Single-Phase Induction Motors.—The single-phase induction motor, consisting of a squirrel-cage rotor and a polyphase stator winding fed from a single-phase supply through a phase-splitting device, is well known. In the past the phase-splitting starting device has usually consisted of resistance and reactance, but in an improved form recently developed, and known as the capacitor motor or condenser motor, a condenser is employed in place of the reactance. The starting torque of the motor is thereby much improved, and the operating efficiency and power factor are high, particularly if the condenser is kept in circuit while running. Unfortunately, the cost of the condensers limits the application of this design to small sizes of motors.

Speed Control of Induction Motors.—For the speed control of large induction motors the well known Kramer and Scherbius auxiliary machines continue to be employed, but for smaller power units the a.c. commutator motor described below affords the most satisfactory solution.

A.C. Commutator Motors.—While the a.c. commutator motor is not new, general appreciation of the advantages to be obtained from the improved modern designs appears to be quite recent.

Variable-Speed A.C. Commutator Motor (*Shunt Characteristic*).—While speed variation can be obtained with the slip-ring type of induction motor, such a machine is not economical on varying-speed drives, because speed variation produced in this way involves power wasted in the resistances. It is not applicable where the speed to which it is adjusted is required to remain constant with changing loads, because, where resistance control is used, for any particular setting the speed varies with the current flowing through the resistance, and consequently with the load. The variable-speed a.c. commutator motor has been perfected to satisfy these conditions, being readily adjusted to any desired speed over a wide range, the speed so selected remaining constant with varying load, while the motor operates with high efficiency and high power factor.

Starting and speed control are simple, as the speed control is obtained by moving the brushes, whereas with the ordinary slip-ring induction motor a multi-contact switch and resistance are required, the switch having a number of control contacts corresponding to the number of speeds required.

The modern tendency to adopt the variable-speed a.c. commutator motor in connection with paper-making machinery and for newspaper printing-press service is due to these special characteristics.

Structurally, it is an induction motor in which the rotor carries the primary winding, fed through slip-rings, and also carries a second winding, known as the regulating winding, connected to a commutator. Two sets of brushes bearing on this commutator are connected to the starting and finishing ends respectively of the three phases of the secondary winding which is wound on the stator.

Thus the commutator winding impresses in the secondary circuits a voltage which is varied to obtain the desired speed adjustment by varying the angular separation of the two sets of brushes, while suitable movement of the two sets of brushes together round the commutator controls the power factor. For lift operation the brushes are moved automatically as the speed changes.

Simplified Forms of the Type.—For applications in which the foregoing characteristics are not all required, the following simplified forms of motor are provided:—

A.C. Commutator Motor for Power-Factor Correction.—When only power-factor correction is required without speed variation, one set of brushes is omitted and the commutator reduced in size. Power factor is then controlled by the remaining set of brushes. The motor can be provided to work at unity or with leading power factor up to practically zero (leading). The speed characteristic of this motor is similar to that of the ordinary induction motor. If speed regulation is required, it can be obtained by inserting resistances in the secondary circuit, as with the slip-ring motor.

Alternative types of this machine are available; with some, the high power factor is maintained throughout the range of load, while with other makes it is maintained only at the higher loads.

Intermediate-Speed Motor.—The ordinary induction motor operates at certain definite speeds determined by the number of poles and the supply frequency. For operation at a speed intermediate between these induction motor speeds, a special form of a.c. commutator motor is available; such machines are particularly useful when replacing d.c. by a.c. drive. As speed variation is not here required, the construction becomes simplified while providing operation at an exact speed with good efficiency and power factor.

Motor with Series Characteristic.—For certain duties in which the load is practically constant for any particular speed, as with fans and centrifugal pumps, a simplified form of motor is provided in which one rotor winding is omitted, the stator and rotor being coupled in series through a transformer. Different speeds may be obtained by brush shifting; sometimes a number of transformer tappings are provided to increase the range.

Single-Phase Commutator Motors.—The ordinary "repulsion" motor has been known for many years both in the plain and reversing types. This motor has a characteristic similar to the ordinary d.c. series motor, that is, the speed varies considerably with the load. The constant-speed characteristics of the shunt-type motor have been obtained by an improvement which consists in embedding a squirrel-cage winding below the commutator windings in the rotor. The effect of this squirrel-cage winding is to give almost constant speed from no load to full load; the large starting torque of the repulsion-type of motor is retained, commutation is improved, and the motor operates with a high power factor. Reversing is accomplished, as in the repulsion motor, by reversing the connections to one section of the stator winding.

This motor has proved particularly suitable for the operation of lifts, cranes and hoists, owing to its large starting torque and small drop in speed between no load and full load.

Synchronous Motors.—While the ordinary salient-pole type of synchronous motor is very successful in the majority of cases, there are certain applications requiring a starting torque higher than that obtainable from this type of machine with reasonable starting current. For such duty the new form, known as the synchronous induction motor or auto-synchronous motor, is available. Structurally, this is similar to the induction motor with wound rotor, slip-rings and external variable resistance, but with a d.c. exciter provided in addition. The machine is started as a resistance-controlled slip-ring motor. When it has gathered speed, d.c. excitation fed to the rotor windings brings the motor into synchronism, after which it continues to operate as a synchronous motor.

High-Frequency A.C. Generators.—While machines of this type for the power supply of radio stations are now almost entirely superseded by valve generators, a new demand for high-frequency alternators has developed in connection with the rapidly extending use of high-frequency induction furnaces, special applications, requiring the use of high-speed motors, the production of ozone, and other electrical processes. Both the salient-pole and the inductor types of field are employed in high-frequency alternators now provided for these purposes.

Constructional Improvements.—The modern improvements in constructional features and in methods of cooling discussed above under direct-current machines apply equally to alternating-current machines.

(c) STARTING AND CONTROL GEAR.

Startors and Regulators.—For moderate and large sizes of motors, both d.c. and a.c., and for medium voltages, the drum type of startor is becoming more generally used with non-reversing motors, starting infrequently, where formerly the face-plate type of switch was used. The modern form of startor consists of a drum-type switch for cutting out the resistance, and electrically operated contactors for closing the line circuit, the arrangement being such that the circuit is not broken on the resistance switch-contacts but always on the contactor, which is specially designed for the purpose. The result is that there is very little wear on the resistance switch-contacts.

There are signs of a tendency to use overload relays of the thermal type in place of those of the coil type, or in addition to the coil type, for motor startors. By this means the overload device has a characteristic more like that of the machine than can be provided by the coil-type overload relay.

Two alternative forms of protection may be used. In one the thermal overload relay only is used in the startor and a short-circuit protection is provided in the coil overload of a group switch. This is particularly suitable where a number of switches of very small capacity are used, and where unnecessary expense would be incurred in making each one suitable for rupturing the maximum capacity of the circuit. In the other case, where the switch is capable of rupturing the maximum capacity, a thermal overload relay is used to protect against relatively small overloads of long duration, and a coil trip set for high overloads is provided for tripping under short-circuit conditions.

(2) POWER TRANSFORMERS.

Size of Unit.—The outstanding progress in England is in the increase in the kVA capacity of the units which British manufacturers are able to build for transport over British railways through our small tunnels, and complete in their own tanks except for such external parts as bushings and radiators. Whereas in 1926 this limit of size was estimated to be about 30 000 kVA at 66 000 volts, units are now being built up to and including 75 000 kVA to operate on the national 132 000-volt network. The transport of the largest units is opening up new problems for the railway companies, who are actively engaged in designing entirely new types of vehicles for this service.

Method of Cooling.—These large units are oil-immersed and self-cooled up to about half rating, i.e. 30 000 kVA, forced cooling being adopted at full rating and the auxiliary cooling being automatically started by devices which are controlled by the internal temperature of the windings. (It is now recognized that internal temperatures of windings are of more vital importance than oil temperatures.) The auxiliary cooling sometimes employs a forced oil circulation through separate oil coolers, in which case the preferred cooling medium is now generally an air blast (except on hydro-electric schemes), rendering the installations independent of water supply. A more popular scheme, however, is that by which air jets are directed upon the transformer radiators; this facilitates the provision of self-cooled rating amounting to a large proportion of the full rating.

Air-blast cooling without oil immersion is now confined chiefly to extensions of existing plant. Objection to oil immersion as a fire risk is now seldom raised, but where it is, objection is taken, quite reasonably, to air blast also.

High Efficiency.—Many operators are now demanding self-cooled designs for the largest ratings, not merely in order to save the running cost of auxiliary plant, but because in their opinion the increased capital cost is more than offset by the gain in efficiency. As a corollary, the high efficiency demanded results sometimes in a design in which forced cooling shows no capital economy. The demand for high efficiency has caused designers to study in more detail the causes and accurate estimation of stray losses.

Three-Phase versus Single-Phase Units.—It is of interest to note that the two biggest transformer units yet built in the world are both 3-phase units, viz. a 50-cycle, 100 000-kVA unit in the short-circuit testing laboratory of a large Continental firm, and a 25-cycle, 83 333-kVA auto-transformer supplied to Buffalo, U.S.A. In this latter transformer, the high-voltage winding was in two independent sections connected to separate bus-bars in order to reduce the magnitude of possible short-circuits on the system.

British practice, like Continental, is distinctly in favour of 3-phase as against single-phase units, even for the largest capacities. The saving in space and switch-gear is considered to be particularly important.

In the Dominions, owing to their greater distance from the manufacturers, and to the inferior transportation facilities and the need to carry more spares at minimum cost, there is an equally decided preference for single-phase units. While these arguments will not apply to the United States, the industry there also prefers single-phase units.

Earthing.—Continental practice has crystallized in the use of a high reactance between system neutral points and earth. The reactance is adjusted to balance the line capacity under conditions of fault on one line, with the object of (1) stopping the fault current immediately if it is merely an arc-over, and (2) permitting operation with one line earthed if the fault is more serious.

American and British practice, on the other hand, favours solid earthing of the neutral through a minimum impedance, with the object of switching out immediately any line on which a fault occurs. On the higher-voltage systems, solid earthing without any impedance has been employed, but on the larger systems in the United States it has been found that, simultaneously with system faults, telephone exchange operators have received severe acoustic shocks, and some change in practice may be necessary.

Surge-resisting Design.—The prevalence in the United States of single-phase units combined with solid earthing of the neutral has resulted in the development of a "non-resonating transformer," characterized by uniform stress distribution throughout under transient voltage conditions, rendering possible the elimination of end-turn reinforcement, one of the bugbears of general transformer design.

High-Voltage Testing Transformers.—Similar principles have been independently applied, with great success in England and on the Continent, to high-voltage testing transformers up to 500 000 volts in one tank, and in a single-tank unit now under construction for 1 000 000 volts to earth. A 3-unit testing set giving 1 000 000 volts to earth has been installed at the National Physical Laboratory. An American University has a 6-unit equipment giving, at 50 cycles, 2 100 000 volts with centre point earthed; and the General Electric Co., Pittsfield, U.S.A., have made impulse tests at 5 000 000 volts.

Transients.—Considerable research is in progress on the propagation of transients over transmission lines and through transformer windings, and much attention is being paid to the correlation of the insulation throughout systems so that no parts are unduly weak in comparison, or others of unnecessary cost or dimensions. It is recognized that where overhead lines are employed and traverse districts subject to lightning, transient voltages must be considered as well as rated operating voltage. Allied with this has been the adoption, notably in Sweden and the United States, of an ultimate safety protective discharge-gap adjacent to expensive apparatus such as transformers, to act as a final relief to the system if abnormal voltages occur.

Tap Changing.—Tap changing under load is now a common feature of large transformers. The range required is often such as seriously to complicate the design, and special arrangements of windings are developed to ensure a minimum of mechanical forces while meeting requirements as regards reactance and high efficiency.

Separate boosters are almost inevitable when there are added the complications of "three windings" transformers with two output windings and definite reactance requirements for each to be simultaneously met under different loading conditions, or, again, when the lower-voltage winding is 125 000 volts or more.

General Construction.—Improvement in manufacturing methods has rendered possible the production of windings in which the shrinkage is completed before final assembly, thus in many cases permitting the elimination of adjustable coil-clamps.

Paper-covered wire is now almost universal, and cotton coverings are restricted to low voltage and small outputs.

The internal temperatures of cores have been studied, and methods of construction adopted giving improved results both from mechanical and thermal viewpoints.

Drying Out.—It is now common practice to transport transformers to site in oil in their own tanks after drying out at the makers' works; by this means long periods of drying out on site are replaced by a speedy conditioning or merely a check of condition. Varnish impregnation of the insulated windings is claimed by some makers to facilitate this, while others use oil impregnation also.

Oil.—Due to the general use of oil complying with the British Standard Specification, and to the general adoption of the conservator type of transformer in large sizes, oil sludging is no longer a serious problem.

Transformer Protection.—Attention has been given on the Continent to the development of means for detecting an incipient fault in the transformer by means of the gas produced thereby, this gas being made either to operate a float or to displace oil in an upper vessel and operate a photo-electric relay. These devices have found little favour in Great Britain and the United States, reliance still being placed on the well-known systems of balanced-relay protection.

(3) CONVERTORS AND RECTIFIERS.

(*a*) ROTARY CONVERTORS.

Rating.—The average size unit demanded has increased. Typical sizes representing modern practice would be:—

4500-kW 187·5-r.p.m., 1 500-volt, 3 000-amp., 25-cycle rotary convertors for heavy traction work, these machines having the normal overloads for such service.

3000-kW, 333-r.p.m., 440-volt, 6 800-amp., 50-cycle rotary convertors for power and lighting.

2500-kW, 300-r.p.m., 250-volt, 10 000-amp., 40-cycle rotary convertors for electrolytic work.

Voltage Regulation.—Voltage regulation by reactance control has been used on the bulk of the machines installed. Where the range in voltage was larger than could be conveniently and economically controlled by this method, induction regulators, rather than boosters, have been used for the purpose of giving the larger range required. This method has the advantage that the commutation of the machine is not disturbed when varying the voltage delivered by the rotary convertor at the d.c. end.

Starting.—The greater proportion of machines installed have been provided with starting induction motors, and arranged for self-synchronizing rather than starting by taps from the main transformer. This method has the advantage of low starting current, no sparking at the commutator during the starting period, and simplification of the main transformer design by the omission of taps. It also has the added advantage that, should the commutator or slip-rings require grinding, the starting motor is available for this service.

Efficiency.—The efficiencies of rotary-convertor plant have been so maintained that they still remain the most efficient method of converting alternating to direct current for voltages up to 600 volts on load factors even as low as 33 per cent. Machines of 1 000 kW capacity, and larger, have been installed with efficiencies, including the transformer, of 95 per cent on full load, this efficiency including all load losses. The efficiency of 500-volt to 1 500-volt rotary convertors on full load, including transformer and including load losses, may be taken as 94 per cent, this figure representing average good design.

1 500-*volt Rotary Convertors*.—Several large schemes, involving generation of direct current at 1 500 volts by 50-cycle rotary convertors, have been installed. Where the size of unit has been 1 500 kW and above, two 750-volt machines in series have been installed. Where the size of unit has been below 1 500 kW, single-armature machines for this duty have been constructed.

The majority of machines for 1 500-volt service have been constructed without the use of commutator lugs, and with a fan to produce a blast of air over the commutator surface. Machines constructed along these lines have proved that 1 500 volts can be obtained from 50-cycle rotary convertors with an exceedingly low cost of maintenance.

The contract for one recent railway electrification scheme at 1 500 volts (d.c.) covers the installation of twenty-six 2 500-kW units generating at 1 500 volts, each unit consisting of two 1 250-kW, 750-volt convertors in series, these machines having overloads of 75 per cent for 1 hour, and 3 times full load for 5 minutes. These machines were constructed for reversible operation to take care of regeneration on the trains.

(*b*) MOTOR CONVERTORS.

The proportion of converting plant in the form of motor convertors has increased during the last few years, mainly owing to important detail improvements.

The speed of motor convertors was for a long time limited because the current per brush arm was restricted to from 800 to 1 000 amps. If attempts were made to increase the current per brush arm beyond this figure, commutation became delicate and difficult.

Armature windings have now been developed which have considerably raised this limit without reducing the robustness and reliability of the earlier machines. This has resulted in cost and efficiency becoming more comparable with those of the rotary convertor. In fact, motor convertors have been installed with efficiencies as high as the highest-efficiency 50-cycle rotary convertor equipment.

Motor convertors having the following rating have been manufactured: 3 000-kW, 428 r.p.m., 460 volts d.c., 6 000 volts a.c., with normal temperature-rise. A 3 000-kW, 500-r.p.m., 490-volt d.c., 6 750-volt a.c., maximum rated motor convertor is also under construction.

It is possible with machines designed along these lines to obtain greater output per sq. ft. of floor space than with any other type of converting machinery.

General.—Material detail improvements in windings, brush-gear and brushes have been effected, so that operating engineers should no longer be worried by any form of marking of commutators.

While the speed of machines for a given output has increased, a good deal of research work has been done with regard to noise, with the result that there has been a marked reduction in the noise emitted from rotating machines, even though speeds have materially increased. Manufacturers who have studied this problem appear to be acquiring almost complete control of this aspect of design. Also, in line with this, steps are being taken to render substations more noise-proof. Many of the more important stations are also fitted with filtering equipment for the purification of the incoming air.

Automatic Operation.—There has been a material increase in the number and size of automatic equipments. More protective devices are usually provided for the machines in those unattended substations which are automatically started by remote control than in the attended substations, and a fault is more quickly removed from a machine by this automatic means than in an attended substation.

In order to provide equivalent protection in an attended substation the cost of the equipment would be nearly as high as for an unattended substation, so that the logical tendency is to make the substation entirely automatic and save the cost of the attendant. Such stations may be controlled by pilot wires from the nearest manually operated substation, or a group of such automatic substations may be controlled from a central office.

(*c*) MERCURY-ARC RECTIFIERS.

The steel-clad type of mercury-arc rectifier has made little advance in this country. Progress has been made abroad, particularly in details giving improved reliability of operation.

An electrified German railway has a 1 200-volt automatic-rectifier substation provided with mercury-arc rectifiers, each of 450 kW continuous capacity and able to handle peak loads up to 850 kW.

There has been considerable activity in connection with the glass-bulb type of rectifier, particularly in the extension of its application to automatically controlled plant.

(*d*) HIGH-VACUUM THERMIONIC RECTIFIERS.

The application of this type for the generation of high-voltage d.c. anode supply in wireless transmitting stations has become general. It is also now extensively employed for rectifying the anode supply from a.c. mains in broadcast receiving sets.

(*e*) HOT-CATHODE MERCURY-VAPOUR RECTIFIERS.

These are a new development which may ultimately supersede the high-vacuum type thermionic rectifier in high-voltage wireless transmitting stations; they also promise to become an active competitor of the mercury-arc rectifier in other fields of high-voltage work.

(*f*) COPPER-OXIDE DRY RECTIFIERS.

These have proved remarkably successful for low-voltage battery charging from a.c. mains. An alternative form is the copper-sulphide dry rectifier, the use of which is extending.

(4) POWER-FACTOR CORRECTORS.

The chief advance in power-factor improvement is the rapidly extending utilization of compensated induction motors and synchronous motors of both the salient-pole and synchronous induction types discussed above under a.c. motors. Apart from this, several alternative means are employed to improve load power factor, chiefly static condensers, synchronous motors or synchronous condensers, and phase advancers (used in conjunction with large induction motors).

Static condensers are either directly connected to groups of motors or are employed in banks operating on the supply busbars or feeders. In the latter case they have usually been brought into and out of service by means of time switches, but an improved method is to employ relays controlled by the magnitude of the busbar or feeder load current.

Synchronous condensers hold their own limited field in connection with large plants.

The practice of compensating individual large induction motors by means of auxiliary phase advancers, generally of the Scherbius type, is steadily growing.

An interesting recent development in the United States is the "series capacitor," consisting of a bank of oil-immersed static condensers connected directly in series with the line and compensating for transformer and line reactance at all loads. Automatic protective devices by-pass the condenser under short-circuit conditions.

Experience indicates that the series capacitor increases the stability as well as the power-carrying capacity of long lines, and improves the voltage regulation and the division of load between parallel lines.

(5) MARINE APPLICATIONS OF ELECTRICITY.

The application of electricity on board ship has now reached the stage when its reliability is accepted and unquestioned.

This statement is proved by the success of recent vessels equipped with electric drive and also by the fact that practically all vessels, whether propelled by steam or internal-combustion engines, depend on the reliability of electric machinery for operating vital parts such as steering gear, scavenger blowers, and circulating and lubricating pumps.

Diesel-Electric Drive.

The flexibility of the power distributing system and the availability of the current wholly or in part either for one or for several simultaneous duties are of major importance in certain classes of vessels. The oil tanker uses the Diesel-engine-driven generators for propulsion at sea and for driving the heavy oil pumping equipment in port. The system also applies with equal advantage to ships which have extensive deck-unloading equipment, or to fire-boats, salvage boats and dredges in which a large amount of power is required for other than propulsion purposes.

On tugboats, ferries, tankers, cargo vessels, cutters, submarine depot ships, cement carriers, yachts and dredges, the economy and convenience of the system are very pronounced.

An example of the Diesel-electric drive is that of the oil tanker "Brunswick," completed in 1928 and owned by the Atlantic Refining Co. This ship is propelled by a single-screw d.c. motor of 2 800 s.h.p., to which power is supplied by four 600-kW Diesel-driven d.c. generators connected in series. Each of the four Diesel engines is direct-coupled to one 600-kW generator and one overhung 75-kW d.c. auxiliary generator which supplies power for various auxiliary purposes, or, alternatively, for exciting the various field circuits of the several machines.

The speed of the propeller is varied by alteration of the generator voltage by means of a potentiometer rheostat, and the direction of rotation is changed by reversing the generator voltage. The potentiometer rheostat can be operated either in the engine-room or, by remote control, from the navigating bridge. The latter consists of a follow-up device, so that the navigating officer merely moves a lever which is in the form of the usual bridge telegraph, and the rheostat automatically, and at a predetermined rate, takes up a position which gives the desired propeller speed. Means are usually provided to prevent power being applied to the propeller too rapidly, so that the engines and generators do not become overloaded during manœuvring.

If it is required to run for long periods at reduced speed—for example, during a fog, or when running to a schedule or effecting repairs or adjustments on the Diesel engines—one or more of the generators may be cut out of circuit and the engine stopped. This is accomplished by de-energizing the generator field and short-circuiting its armature, so as to maintain the circuit of the propeller motor intact. The generator can then be disconnected by opening the switches. These operations can be performed without stopping the propeller, and in a similar manner extra generators can be brought into service. All switches are interlocked to render them mistake-proof.

The system is usually earthed through a circuit-breaker and resistance at one point, with alarm devices to give warning should an accidental earth occur elsewhere.

The "Brunswick" has proved the reliability and economy of electric drive to the satisfaction of the owners; this is further emphasized by the fact that two more identical tankers have been ordered.

Turbo-Electric Drive.

This form of drive can claim advantages such as silent running, reliability, economy, and quick response to orders from the bridge. It is only by actually taking a voyage on a turbo-electric vessel that the silent running and absolute comfort can be realized.

An example of turbo-electric drive is the well-known "Viceroy of India," which started her maiden voyage in March, 1929, and is owned by the Peninsular and Oriental Steam Navigation Co.

The main propelling machinery consists of two separate turbo-alternators, each with its own condensing plant and auxiliaries, supplying current to two 8 500-h.p., 109-r.p.m., 3 000-volt synchronous motors which are direct-coupled to twin propeller shafts. The propeller motors have a squirrel-cage winding embedded in the pole-face of the rotors for starting purposes.

A contactor cubicle, including air-break reversing contactors for effecting the necessary phase reversal for changing direction of rotation of the propeller motors, is provided to control the power from one or both alternators to both motors. With synchronous motors it is also necessary to have contactors to break the alternator and motor fields.

All manœuvring, i.e., starting and reversing, takes place at approximately one-fifth of full speed. The reversing contactors and field contactors are operated by levers interlocked with a third lever for varying the speed of the turbine. When starting from rest, the reversing lever is first placed in the direction required and the manœuvring lever is moved to the first starting position. This energizes the alternator field at a field current in excess of the normal running value. The propeller motor functions as an asynchronous machine and accelerates almost up to synchronous speed. The field of the motor is then energized and the motor pulls into synchronism, when the alternator field is reduced to normal. The control gear is fully interlocked to avoid mishandling and to prevent access to the high-tension switchgear without first isolating the supply. Various temperature and earth alarms are also provided.

At reduced powers one turbo-alternator only is required for supplying current to both motors: thus maximum economy in fuel, both at full and reduced power, is obtained, and this is a great advantage in a vessel which does part of its voyage at less than the maximum speed and power. The reserve power can be quickly brought into use when required, for example, if the ship is delayed by heavy weather or fog.

The trial results, the results in service and the minimum amount of time this vessel has been in port clearly indicate the many advantages the electric drive can offer.

It is beyond the scope of this paper to discuss the economies of electrical propulsion. In general, the question as to whether electrical drive is used depends upon the purpose for which the vessels are intended, and also upon the enterprise of the chief superintendent engineers of the various shipping companies.

AUXILIARY ELECTRIC DRIVE.

The application of electricity has come to the assistance of some of our large vessels driven by reciprocating engines, and great strides have been made with this form of auxiliary drive.

The exhaust from the reciprocating engine is led into a turbine, and useful work is done by further expansion of the steam. The turbine is coupled, either direct or by means of mechanical gears, to an electrical machine, and, if required, a generator suitable for supplying auxiliary power and lighting can be connected in tandem.

The electrical machine supplies current to a motor on the main propelling shafting, and by this means the reciprocating engines are assisted in turning the propeller. Approximately 25 per cent of the total indicated horse-power of the existing engines can be fed back to the propeller shaft.

In the case of a twin-screw vessel, this drive has an additional advantage over the well-known mechanical auxiliary drive, in that only one turbo-alternator need be fitted and the power divided equally between the two screws by a motor connected in each propeller shafting.

AUXILIARY MACHINERY.

All kinds of machinery, such as winches, windlass, steering gear, pumps of all descriptions, scavenger blowers, fans, compressors and refrigerating machinery, are driven electrically, and electric cooking and heating are now quite common on modern liners.

On the "Viceroy of India" the winches, windlass, capstans, engine-room pumps, refrigerating machines and forced-draught fans are electrically driven on the constant-current system. Another application of the constant-current motor is for driving the winch which operates the life-boats. Recently many orders have been placed for this type of motor. The use of this new system is increasing rapidly, and in the next few years considerable use of this system for the above-mentioned duties is anticipated. Even for main propulsion it is ideal in some specific cases.

GENERAL.

It is of interest to note that, at the present moment, 4 large turbo-electric liners, 2 ferries and 2 yachts using turbo-electric drive, and 1 tanker, 3 tugs and 3 ferry-boats using Diesel-electric drive, are being built by a well-known company in America. In this country, orders for 3 turbo-electric vessels, 2 Diesel-electric vessels, and 3 auxiliary turbo-electric equipments have been placed with a well-known electrical company. The placing of so many orders, some of which are repeat orders, clearly indicates the path which many shipowners have until recently hesitated to follow.

(6) ACCUMULATORS.

(a) LEAD-ACID BATTERIES.

The old-established makes show progressive improvement in quality without any radical departures, except perhaps the perfection of the so-called solid electrolyte—a gelatinous substance saturated with acid which is now extensively used in portable cells.

In a new make a special process is employed which is claimed to give extremely low internal resistance and to obviate the tendency to formation of sulphate. The makers claim that these new batteries can be short-circuited with impunity and left in a discharged state for any length of time without impairing their capacity and efficiency. Severe independent tests by responsible laboratories and individuals appear to substantiate these claims.

(b) IRON-NICKEL-ALKALI BATTERIES.

The recognized features of batteries of this type are their light weight for a given output, robust construction, resistance to vibration, absence of acid fumes, freedom from sulphating or kindred troubles associated with standing idle, immunity from damage by overloading, short-circuiting or reversed charging.

These properties have led to their extensive adoption for special purposes, such as train and car lighting, aircraft lighting, life-boat wireless equipment, and other occasional emergency services.

Recent improvements in this type have been in the direction of improving the length of life and reducing the weight, volume and cost for a given output. The makers now claim to have overcome the difficulty of inactivity at low temperatures.

DOMESTIC APPLICATIONS OF ELECTRICITY.[*]

By C. G. Morley New, Member.

Dr. Ferranti, whose views are always regarded with more than ordinary interest, has stated: "We have learnt that electricity is before all things the greatest labour saver, and a little investigation shows that in the application of electricity to the requirements of the home we have open to us a field almost unimaginably wide."[†]

The great potentialities in this field have been fully recognized in recent years and, almost without exception, supply undertakings have been concentrating on this development. Undertakings which for many years have been associated more particularly with the development of supplies for power purposes are to-day equally active in the field of domestic supplies. The growing importance of these supplies has been commented on by the Electricity Commissioners in their Annual Reports,[‡] from which the following figures have been taken:—

Private Lighting and Domestic Supplies.

	1924–5	1925–6	1926–7
Increase, in millions of units	—	206·9	198·9
Percentage of total sales ..	20·3	22·2	24·6
Revenue as a percentage of total revenue ..	49·0	51·4	49·7

When it is borne in mind that a relatively large amount of labour and material in the way of cables, service and installation accessories and domestic appliances is required to obtain this additional output, compared with that in other directions, the importance of this development to the manufacturing and contracting branches of the industry will be appreciated.

It is pleasing to record that reliable and efficient domestic apparatus of all descriptions is now manufactured in this country and that the resources in this connection have been considerably increased in recent years.

Statistical information regarding the total amount of domestic apparatus in use is not available, but the *Electrical Times* has from time to time published details of progress made by individual undertakings. The following figures are obtained by summarizing the particulars given in 1927 and 1928 of 35 undertakings.

	1927	1928	Increase	Percentage increase
No. of cookers ..	22 442	29 147	6 705	29·9
Cooker connections, kW	129 474	172 048	42 574	32·9
Apparatus other than cookers, kW	315 036	395 956	80 920	25·7

Returns which are now being published show that this percentage increase is being maintained.

Popularizing the Domestic Use of Electricity.

During the winter season of 1926–27 the British Electrical Development Association conducted a campaign directed to better lighting in the home, and this was followed in 1927–28 by schemes to popularize the domestic applications of electricity. It was reported that 122 demonstration houses, exhibitions and special electrical demonstrations were organized, mainly through local committees, and that an attendance of approximately 1 200 000 persons was secured. An interesting and satisfactory feature of this campaign was the enrolment of nearly 250 volunteer lecturers, resulting in 274 lecture engagements being reported. The Association again in 1928–29 directed its energies to domestic apparatus, by a scheme of national advertising linked up with a monthly programme for local activities such as posters, showroom window-dressing suggestions and publicity leaflets. Co-operation in a scheme of this sort meant that numerous parts of the country were giving publicity to a particular item of domestic electrification at one and the same time. The outlet campaign referred to below is the subject of the Association's special activities for 1929–30.

The Electrical Association for Women is firmly established and is doing excellent work in assisting development in the domestic field. In addition to the usual lecture programme the first national campaign was carried out in 1928, having for its object the provision of more electrical outlets in the home. A number of meetings were held throughout the country to discuss a draft specification issued by the Association. At these meetings there were, in addition to those connected with the electrical industry, representative architects and builders, and considerable publicity was thus obtained. There is further definite evidence, not necessarily arising entirely out of this particular campaign, that speculative builders in most districts are now providing more adequate facilities for the use of sundry electrical apparatus throughout the house, where hitherto at the most a 5-ampere plug and socket was provided in the hall and on the bedroom landing. The Association has 20 branches and over 3 000 members, and publishes an interesting and instructive monthly journal, now in its second year, entitled *The Electrical Age for Women.*

Facilities for Instruction in Schools.

The Electrical Association for Women is making a survey of the kind of domestic electrical apparatus that exists in girls' schools and domestic science centres. The Association feels that, with the exception of a few progressive centres, the equipment is out of date.

This is part of an endeavour to induce educational authorities to provide facilities for senior scholars and teachers to obtain some simple instruction on electrical matters. Generally, educational authorities still regard electrical equipment in the nature of a luxury, but the town of Barnsley is an outstanding example of progressiveness in this connection. The Corporation, having during recent years brought into operation schemes for hired wiring, and electric cookers and hire-purchase of domestic apparatus, has through its education authority equipped 8 elementary schools with 12 electric cookers, 15 wash boilers and 130 irons, for the purpose of practical instruction in the care and use of apparatus similar to that already installed in a large number of working-class homes.

As a result of a committee (Headmistresses' Employment) set up by the Ministry of Labour, two special courses of training in electrical housecraft have been started at Chelsea and Battersea Polytechnics.

Installation Accessories.

The increased use of bakelite and similar synthetic resins for installation accessories in place of wood, porcelain and metal has been most marked. Switch-covers, ceiling roses, lampholders and galleries are available, and the majority of plug tops and socket covers are made of this material.

The more general adoption of plugs and sockets to the British Standard Specification, and the policy of some supply engineers, have resulted in 15 amperes being the size now generally used for heating and domestic power circuits. The sales of 3-pin sockets and plugs have been increasing slowly, more particularly in the larger sizes, but earthing is to a large extent ignored where plug points are used for reading lamps and small appliances. It cannot be said that there is any definite movement towards a settlement of the debatable question of earthing, as the increased sales of 3-pin plugs and sockets probably only represent between 5 and 10 per cent of the total number of both types installed.

Lighting.

The cost of electric lighting is probably as low to-day as it has ever been. Improved manufacturing methods have provided the user with cheaper electric lamps, and the efficiency of these has been improved by some 3 to 5 per cent. A small preference in price is being given to 230-volt lamps, in order to encourage the adoption of this standard pressure. Lamps suitable for domestic use have been reduced to five sizes, 15- and 25-watt vacuum type and 40-, 60- and 100-watt gas-filled type.

To-day there is a definite tendency for manufacturers to concentrate on the sale of glareless lamps at prices that are in many cases lower than those for clear lamps, and this should result in the near future in the replacement of all clear lamps by obscured lamps for domestic purposes. This movement will go far towards establishing better lighting conditions in the home and assist in the important national problem of eyesight preservation.

Light as a decorative medium in the home is being more and more appreciated, and new materials have been produced which give lighting fittings still greater utilitarian and decorative value. The more general adoption on the part of supply undertakings of the two-part tariff enables the householder to use electricity lavishly for lighting purposes.

Public interest in residential lighting during the period under review has been greatly stimulated by the fitting up by the Electrical Development Association and other organizations of all-electric homes in various parts of the country, the dominant feature of the furnishing being the electric lighting effects.

The new architectural lighting, in which the lighting is built into the fabric of the interior, has not so far been applied to any great extent in the home, but a definite tendency to adopt lighting fittings of a modern type has been noticeable, the units being generally constructed of flat sheets of glass built up into simple geometric forms and supported in light metal frames. The new styles have emanated from the Continent, and an attempt to interest British decorative artists and designers in this development is being made by a prominent electrical manufacturing firm in co-operation with the organizers of the Ideal Homes Exhibition to be held in the spring of 1930 at Olympia, London, by offering prizes to the value of £1 000 in connection with the lighting and decoration of a suite of six rooms.

In general it may be safely stated that a much greater public appreciation of the possibilities of electric lighting is apparent, but the ordinary householder is still considerably hampered in the adoption of many home lighting conveniences by the scarcity of plug points.

Cooking.

Progress in electric cooking is being fully maintained, the business generally being obtained by hiring the apparatus. At least two towns have over 5 000 cookers installed, five between 2 000 and 4 000, and 10 between 1 000 and 2 000.

Considerable improvement has been effected in recent years, both in general appearance and finish—appealing to the public—and in those details that make for reliability and lower maintenance costs—appealing to the supply undertakings. Obsolescence has been a serious factor, and the improvements in design appear to have delayed the downward trend of prices expected from increased business. The general design is, however, settling down, and an effort is being made by the Incorporated Municipal Electrical Association with the assistance of supply company representatives, in conjunction with a group of manufacturers, to standardize certain details based on the considered opinions of the majority of purchasers.

With regard to improvements, vitreous enamelled hobs have proved a boon to user and hirer and are now standard with all makers. Hot cupboards are now general, except for small cookers. The freer use of vitreous enamel, and the avoidance of sharp edges and corners both externally and internally, are noticeable in recent models. A tendency to revert to the fully-enclosed boiling plate was reported in the last review.* The insistent demand of supply engineers for greater reliability has resulted in many manufacturers adopting the fully-enclosed cement-insulated type of boiling plate, which is usually guaranteed for 2 years. In order to obtain the best results, greater attention has to be given to the utensils for use with this type of plate. Aluminium utensils with turned bottoms and guaranteed against distortion are now available. The desire for quicker boiling brought a transformer-operated boiling-plate on the market in 1928, and, as the resistor runs at a red heat, no special utensils are necessary to ensure good results. Its comparatively high first cost has militated against its more general adoption. In order to get a lower input for simmering than can be obtained with heavily-loaded boiling-plates fitted with the usual series-parallel control, an arrangement for inserting an external resistance in series with the boiling-plate has been put forward. In place of fragile and expensive mercurial thermometers on ovens, an all-metal temperature indicator marked in terms familiar to the housewife, instead of temperature, is being fitted by some makers. The question of the disposal of the oven elements, i.e. as to whether these should be arranged for top and bottom heating, side, or side and bottom heating, is still a debatable one amongst supply engineers and manufacturers, although the majority appear to favour the two latter methods. Those who contend that side heating will do all that is required, would probably not object to a little bottom heating, and should a standard method be considered desirable the solution seems to be in this direction.

The development of electric cooking in the United States of America is understood to be ahead of that in this country. It is, however, estimated that 3½ million devices for cooking were sold in that country in 1927, of which only 120 000 (3·4 per cent) were electric. These figures show the possibilities of expansion in this field.

It is usual to supply a self-contained electric kettle with cookers on hire, and it has been found essential in practice to provide an automatic device to prevent damage due to overheating. Considerable attention has been given to this detail, and much ingenuity shown; although many of the early devices proved unreliable, effective and satisfactory ones are now available.

HEATING.

The electric fire still forms the principal application of electricity in the home. The portable type with fireclay fire-bar is very popular and in greatest demand. The imitation coal fire with and without a flame effect is also freely sold. Manufacturers have been giving increased attention to improving the general appearance of comparatively cheap mass-production models. Enamelling has improved considerably and excellent examples with a choice of colours are sold by most makers. Chromium plating has been introduced for reflectors and framework, also cellulose finish, giving unique and attractive colour effects. There is a slight demand for heaters which can be placed in the centre of the room instead of in the fireplace. Fixed fires, more particularly rectangular-shaped, are available for fixing in chimney breasts in place of the open grate. It is not unusual with fixed fires to place the controlling switches at hand-level on the wall, instead of on the apparatus itself.

Domestic heating by electrical means has generally been looked upon as occasional heating with a good diversity factor, the living rooms being heated during winter months by the usual coal fire. This view may have to be modified where a two-part tariff with low secondary unit charge is available. In any case, exceptional climatic conditions are likely to embarass supply engineers where this load is well developed. Extremely cold weather was experienced in this country during the week ending the 18th February, 1929, and a number of undertakings experienced heavy loads and increased outputs, particularly those in residential areas. Increases of up to 120 per cent in output and 85 per cent in maximum load over the corresponding week of the previous year were reported.

Low-temperature heating in one form or another has made tremendous headway in offices, schools, theatres, picture houses, etc., but in the home it has been introduced to only a very small extent. The advantage over central heating of being able to heat individual rooms and control the temperature easily and, if necessary, automatically, is being appreciated. The tubular type, loaded to about 60 watts per foot run and working at a surface temperature of about 180° F., appears to be popular. There are nearly 100 schools, with individual installations up to 130 kW, heated by this system, whereas 3 years ago there were probably not six. At that date the system was experimental and it was not unusual to provide heating chambers and fans in case of failure, but to-day there are cases of new buildings being designed for electric heating only. The first cost of this system is less than that of low-pressure hot-water systems if regard is given to the omission of flues, etc., and the running costs appear to be comparable, with energy at ¾d. per unit. Thermostatic control is necessary to ensure economy.

---

* *Journal I.E.E.*, 1927, vol. 65, p. 360.

An interesting departure from the tubular and panel or plate heaters as commonly known, which operate at comparatively high temperatures, is an electric warming panel which, on account of its low working temperature, readily admits of easy and safe incorporation in the building structure. These panels are designed for a maximum surface temperature of 120–125° F. when fixed horizontally on a ceiling and operated in still air. With automatic temperature control, the temperature averages 85–90° F., if adequate surface is installed in relation to the heat loss. The loading averages 40 watts per sq. ft. of active surface, or 400 watts for a standard panel of 12 sq. ft. The panels are intended, wherever possible, to be sunk into the ceiling, and the finished surface of the ceiling is left flat so that convection currents and " dusting " are eliminated. This embedded type of panel consists of a slab of cork secured to an asbestos-cement board, and to the cork is attached the insulated electric warming element embedded in a rough-faced plastic composition. With the finishing coat of plaster after erection, the total thickness is about 2 in. The makers state that the most economical and efficient method of operating this system is to keep the installation continuously in circuit during the heating season, 24 hours per day and 7 days per week, with thermostatic control, and to install an ample area of surface at the outset. As an alternative to making full provision for occasional spells of extreme cold weather, the system can be installed as a basic warming method for average conditions, being boosted by other means as and when required. The wattage to be installed varies not only with the temperature-rise required but with the amount of glass surface, thickness of walls, amount of exposed surface, and other details. As a rough guide, average figures show a variation from 0·57 watt per cub. ft. and a temperature-rise of 15 deg. F., for such places as garages and store rooms, to 1·67 watts per cub. ft. and a temperature-rise of 45 deg. F. for occupied rooms. These latter figures would meet extreme cold-weather conditions.

In order to take advantage of low off-peak rates, thermal-storage systems using either oil or water as the medium have been introduced. A notable installation is that at the new headquarters of the London Underground Railways, designed to store 16 million B.Th.U. to cover two 4-hour periods. There are four 4 000-gallon cylinders installed (one spare) fitted with immersion heaters having a total loading of 1 344 kW. Heating is carried out by hot-water panels embedded in the concrete of the ceilings. The whole system is fully automatic, the storage cylinders releasing hot water when the temperature of the water in circulation falls below a predetermined figure.*

Another large thermal-storage installation is that at the Polytechnic extension in Great Portland Street, London. In this case, instead of low-tension immersion heaters, a high-tension electrode water-boiler is employed, delivering the hot water to three thermal-storage tanks each 8 ft. 3 in. diameter and 28 ft. long. A 3-phase supply at 6 600 volts, 50 cycles, is taken direct to electrodes immersed in the water space of the boiler. The full capacity of the boiler is 1 800 kW, the present loading being 1 200 kW, and regulation is effected by raising or lowering insulating cylinders surrounding the electrodes. This type of installation has emanated from the Continent and is designed to take advantage of low rates offered for night supplies, in this case 0·27d. per kWh. A relay is provided to put the boiler out of commission should any appreciable current pass to earth.*

WATER-HEATING.

There is increased interest in, and demand for, electrical means of providing hot water, more particularly for use during summer months. The instantaneous geyser type has a limited application, and, although small self-contained storage cylinders (usually lightly loaded) are most useful over sinks and in bathrooms, they are expensive in first cost and should be hired out if much headway is to be made. Immersion heaters fitted in the existing central cylinder connected up with the kitchen range, although a somewhat inefficient arrangement, appeal generally to the public because they are easily applied and work in with existing domestic facilities, such as airing cupboards and points where hot water is required. This arrangement, with thermostatic control and working in conjunction with the kitchen range, is convenient and popular. Efforts are being made by some undertakings to encourage water heating at night, and rates as low as ½d. per unit are offered. Instead of time-switch control, a novel scheme of relays controlled by a street-lighting switching conductor has been adopted by the Ashford Urban District Council for storage heaters; this arrangement ensures that heaters are out of circuit when street lamps are lighted between dusk and 11 p.m. As the heaters are fitted with thermostats, a night load may be expected from this arrangement.

ASSISTED WIRING SCHEMES, AND SHOWROOMS.

Full advantage is being taken of the general powers given by the recent legislation† enabling local authority undertakings (in whose hands is the supply to most of the urban areas) to sell apparatus and fittings. About 270 undertakings have in operation assisted wiring schemes, and these fall broadly into two classes. One provides for limited installations in small tenanted properties, on terms enabling supplies to be obtained without any initial outlay on the part of the consumer, and the other covers any installation of reasonable size and/or apparatus on a straight hire-purchase or deferred-payment scheme, with payments spread over, say, 1, 2 or 3 years. A popular and successful method of operating the scheme for small houses is to recover the installation costs by charging a higher rate per unit through slot meters.

There are some 306 undertakings with 350 showrooms; the majority of these sell apparatus, either direct or through contractors, in addition to carrying out the usual demonstration work. Undertakings acting as distributors over large areas find it necessary to have several showrooms, and a new and interesting feature is the introduction of travelling demonstration vans, complete with their own electricity supply, so that propaganda work can be carried on in scattered areas and before public supplies are made available.

† Electricity (Supply) Act, 1926, Section 48.

"ALL-ELECTRIC" HOUSES.

Additional all-electric and one-coal-fire houses, mostly municipally owned, are reported from time to time. An experiment carried out in Birmingham with three houses built by direct labour to the same plan and specification, except in so far as details were affected by the installation of electricity, showed a saving on the cost of £555 for the ordinary house, of £30 in the case of the one-coal-fire house, and £76 for the all-electric house.*

Details of Typical Installations.

Barnes.—57 small houses, one coal fire in kitchen. Apparatus installed:—Cooker and kettle, wash boiler, 2-kW fire, small bowl fire and flat-iron, all hired for 10s. per quarter. Rateable-value tariff. Maximum annual consumption 6 480 units, costing £25 6s. 7d. Average revenue per house £9 14s. 7d.; average price 0·99d. per kWh (or 1·25d. inclusive of hire of apparatus). Total consumption 106 228 kWh per annum (54 812 in two summer quarters).

Epsom.—120 houses. Apparatus installed:—Cooker and kettle, 10-gallon wash boiler, flat-iron, one 2-kW and one 1-kW fire; total cost, including lighting installation, £4 925. Tariff £2 per annum, plus £1 13s. 8d. per annum for hire of apparatus, plus 1¼d. per kWh through prepayment meters, the fixed charges being collected with the house rent. Annual consumption 142 397 kWh. Total revenue £1 178; average per consumer £9 16s. 4d.; average price 1·99d. per kWh.

SUNDRY APPLICATIONS.

It is most difficult for supply undertakings to keep reliable statistics of domestic apparatus connected, and the following list specially prepared by the borough electrical engineer of Ilford and relating to that undertaking is therefore of great interest as showing the relative development of the different appliances.

Apparatus	Number connected	Load
		kW
Radiators	6 557	11 960
Irons	4 597	1 868
Kettles	1 440	1 440
Cookers	938	4 931
Vacuum cleaners	912	106
Immersion heaters ..	381	737
Sundry apparatus ..	171	273
Charging boards	124	186
Washers	117	232
Boiling-plates and grillers	104	137
Toasters	91	52
Fans	85	15
Hair-dryers	54	30
Geysers	28	141
Total	15 599	22 108

DOMESTIC ELECTRIFICATION IN THE UNITED STATES.

The National Electric Light Association have compiled statistics which show that, at the end of 1928, 19 077 000 homes in America were wired for electricity, this number representing about two-thirds of the total. Approximate figures of some of the electrical appliances in use are as follows:—

Irons	14 500 000
Vacuum cleaners	5 800 000
Washing machines	5 000 000
Fans	4 900 000
Toasters	4 540 000
Coffee percolators	3 500 000
Refrigerators	755 000
Sewing-machine motors	700 000

ELECTRICITY SUPPLY TARIFFS AND METHODS OF CHARGE.[*]

By J. W. Beauchamp, Member.

General

The last report on this subject appeared in the *Journal* about three years ago.[†] Since that time no basic change has been made in methods of charging for domestic supply. The perfect tariff for this purpose is still to seek, but the movement—then noted as important—towards tariffs of the composite type (periodic subscription plus charge per unit of energy consumed) has greatly increased, and the older flat-rate scales have in many cases been modified to imitate the effect of this more modern method of charging.

In framing domestic tariffs there is also a movement towards greater simplicity, with reliance on average results rather than on meticulous care as to the cost in individual cases. In calculating the basis of power tariffs as well as of domestic tariffs, the earlier tendency to regard consumer's load factor as the prime, almost the exclusive, consideration has been modified a good deal, and it is recognized that the receipt of a certain minimum payment per annum per consumer is the first consideration and, once secured, permits a good deal of variation in load factor, time of use, and amount of annual consumption.

The demand for electricity no longer calls for such careful nurture as in the early days; sowing its own seed, namely the satisfaction of the user, it now realizes to almost any supplier costs of a character which do not show so rapid a decline in relation to extended hours of use as in the earlier stages of expansion beyond the use of electricity merely for lighting.

Limits of Consumption.

The use of electricity for domestic purposes as practised to-day in the more advanced areas can result in a consumption of the following order:

Houses of Small and Medium Size.

	Units per annum, average per head	
Lighting	100 – 300	A possible range of 100 to 300 units, up to say 3 000 to 15 000, the figure per head being about one-fifth of these amounts.
Heating (partial)	500–5 000	
Cooking	1 000–3 000	
Refrigeration, power ventilation, etc.	100–1 000	
Water-heating	1 000–5 000	

This range of values excludes the largest houses, where method and cost of working are of small interest to the occupiers and electricity is likely to be used largely for reasons of luxury and beauty rather than for its utility and economy—and also excludes the vast number of homes of people with small purchasing-power to whom full electrification can perhaps offer the greatest comfort and improvement, but can only follow elaborate and costly schemes for the free provision of wiring, apparatus and maintenance.

Between those limits, however, the field is large, and the resultant consumption of energy can have a very marked effect on all branches of the electrical industry and make it necessary for the tariff systems on which the supply is based to be such that almost indefinite expansion of the business can be contemplated with safety.

Cost Determinants.

The attainment of the lowest cost for energy delivered to the consumer depends largely upon a particular mixture or proportion of different classes of load—industrial with domestic, and power with light. Where an undertaking operates successfully in a particular class of business, there may exist temptation to encourage another class for the benefit of the combined load factors and differently timed demands, the sought business being supplied with energy which is, in a sense, a by-product of the existing production. By-product terms can, however, only be applied with safety when the supplier has the power to check output at his will—a condition which does not apply where a tariff is offered in a market which may be almost unlimited.

For these reasons very low tariffs free from all restrictions may stimulate such a demand as would lead to embarrassment, only to be overcome by price advances, probably resented by those who had expended money in adopting new methods on the strength of the low rates at the time offered to them.

Tariffs and Character of Districts.

In rural areas and good-class residential areas of a semi-rural character, the much smaller number of dwelling houses per acre or route-mile and the relative absence of works and shops result in a lower density of demand and less diversity of use, making the cost of distribution a very heavy item. In quite rural areas, even if prosperous, there is also much less demand for light and the consumer has a different outlook on the value of expenditure for reducing labour and inconvenience, in short, an undeveloped convenience consciousness, largely impervious to the advertising which has done so much to sell equipment and service in city areas. Not only do costs vary widely with the district, character and magnitude of business done by the supplier, but the value to the consumer also depends a good deal upon his surroundings—the transformation value of electricity to light, heat and power, is constant, the benefit to the user is variable with his circumstances and habits, and the cost of delivery to him varies very widely in different districts.

---

[*] A review of progress. Reprints in pamphlet form, price 1s. each, can be obtained from the Secretary of the Institution.

[†] *Journal I.E.E.*, 1927, vol. 65, p. 361.

To develop such places is not so much a question of how low a price can be charged, but of how much help, equipment and service can be included for a comparatively high price.

Cost of delivery accounts for much of the variation in tariffs, in different districts, as, for example, between a town area, a " dormitory " suburb, and a purely rural district; whilst the towns again vary widely in cost of generation, business and habits of the people.

Greater uniformity in the charges made for electricity is desirable, since notable differences between the rates and forms of tariff of different suppliers cause dissatisfaction to the users, particularly where areas using widely different rates adjoin.

Probably some unification of policy must precede any widespread similarity of charges. The modern tendency to amalgamate undertakings under a common financial interest will help to bring this about, as will also the derivation, in many cases, of bulk supplies of electricity from or under the control of the Central Electricity Board with its unified system of generation and accounting, which may in time be followed by some amalgamation of distribution interests over large areas.

FORMS OF DOMESTIC TARIFF.

However, progress has been made and, to-day, in any district where the supply of electricity amounts to anything more than an exiguous service of lighting the domestic user need no longer be content with a flat-rate tariff, and if an alternative is not offered he should ask for a method of charging which will enable him to lengthen his hours of lighting and progressively adopt electricity for every other purpose in the home.

In most cases improved domestic tariffs are optional and alternative to flat rates, but it is now competent for electricity suppliers to seek official approval for tariffs of other types and to make them compulsory. The special tariffs generally offered vary, but in essence they amount to the collection of a fixed sum per annum per consumer and, in addition, a flat rate per unit for the energy metered.

The annual fixed charge may be divided into regular monthly or quarterly parts, or be greater in winter than in the summer months. It is assessed on:

(1) Capacity of apparatus connected, or some proportion of it.

(2) Maximum load measured by an instrument, at any time, or at a particular time.

(3) Rent or assessment value of house.

(4) Floor area.

(5) Number of rooms.

(6) An " allowed " maximum load, the supply being interrupted or a warning given if that load is increased.

(7) In some cases the fixed charge (for which no supply is given) is replaced by flat rates in a block tariff, the first annual block of units being charged at the usual lighting rate per unit and the number of units in this block representing the supplier's estimate or experience of a normal lighting supply to the particular house for a year—all further units used in the same year being charged at the low, or heat and power, rate. This is an old method, but simple and acceptable to many who object to any charge which does not cover a certain quantity of electricity.

In some of the multi-part tariffs offered, in addition to the fixed charge a certain block of units has to be used and paid for at an intermediate rate before the low or final unit rate becomes operative. This allows a higher intermediate rate to be collected on the use of small accessories—flat irons and vacuum cleaners, for example —before the lowest rate (needed for heating and cooking) comes into operation. This method has the advantage of helping a small undertaking to introduce a multi-part tariff without making the fixed charge unduly high, and to offer a progressive encouragement to the consumer as the latter gradually electrifies his home. Each of these methods has some disadvantages, but all of them are superior to the older system with separate rates and metering for different use of the supply to the house.

In comparing methods, local conditions must be considered, and, provided that a fair measure of equity as between consumers is achieved and that the tariff enables the supplier to contemplate large resulting extensions with safety, there can be no doubt that the method which is the simplest for the supplier's staff to operate and for the consumer to understand is the best.

Although method (7) above has been in use in but a few undertakings, it has stood the test of experience, and its recent adoption in a slightly modified form by a very large and progressive company seems likely to direct attention again to its great simplicity and appeal to the user.

The perfect multi-part tariff for domestic use should record the consumer's maximum demand, the time of occurrence in relation to the undertaking's station and local peak-load, and the diversity of his demand in relation to that of other consumers—an impossibly complicated task which, if achieved, would still leave the consumer uncertain, in advance, of his fixed charge.

The practical alternative, namely, to assess by some simple standard a reasonable annual charge, is sufficiently accurate, but if it is to result in increased domestic business and an improved load factor the amount of the fixed charge must be limited to the annual cost, at the local rate, of normal lighting (less only the cost of normal lighting units at the low unit rate), this fixed charge becoming, if desired, a minimum annual payment. It may then (*a*) be followed by a limited number of units at some price intermediate between the lighting and the heating or power rate, or (*b*) be associated with a single low rate per unit for all purposes. It is better to use method (*a*) than to employ (*b*) with too high a fixed charge, as in this case the tariff may attract the large user, whereas it should offer a progressive attraction to all directly the limit of " normal lighting " is exceeded. Many of these multi-part tariffs have, for this very reason, failed to bring about any notable increase in domestic electrification, often, indeed, entailing to the meagre user a higher average cost than the alternative flat rates. In this respect tariffs of class (7) have the real advantage that the consumers who venture to adopt them cannot pay more than the standard flat rate for lighting, the minimum payment per annum being usually only the statutory minimum in force in the district; yet the consumers are offered the fullest encouragement to electrify their homes in a progressive way.

PREPAYMENT METHODS.

Prepayment Meters.—Re-housing and the demand amongst the working-class population for better home conditions have opened up to the electricity supplier a very large class of customer of small purchasing power and unaccustomed to any periodic payments. The supply of electricity to such property must be on a cash basis, and the prepayment meter, which would be regarded as a nuisance by people better situated, is actually welcomed by the poorer consumers. Unfortunately, with these meters it is difficult to charge on anything but a single flat rate; the separate collection of a fixed charge is as difficult as the collection of the whole account in that way and, although in some cases a fixed charge has been collected with the rent, leaving the slot meters only to collect the unit charges, no great progress has been made in offering the prepayment consumer a chance of using electricity for all purposes and yet of paying the whole of his account through a simple meter and in advance.

This problem is the more important, since the smallest consumer can be satisfied with so little energy for lighting (50 to 100 units per annum) that the business is hardly remunerative, especially if the installation is connected to an underground network and is associated with some form of "assisted" wiring, as is often the case.

Prepayment meters are now available which will collect a periodic fixed charge in relation to the electricity supply and/or on the hired wiring or apparatus and, in addition, will deliver units against further payments by coins in the slot. There are also types which rely on a time-registering mechanism and need the insertion of a coin at fixed intervals (e.g. once a week) to keep the switch closed and, in addition, of coins to cover the electricity used.

The technical difficulty of collecting a multi-part tariff through the medium of prepayment meters has to some extent been overcome, and such meters are already in use; for the moment, the difficulty lies in their relatively high cost and the need, in the case of small consumers, generally to provide wiring and apparatus on easy hire or hire-purchase terms.

NON-METERED SUPPLIES.

When this very small business was first catered for, there was little prospect of a heating and cooking demand from this class of user and the difficulties were met to some extent by the "contract" system of charging. In this a fixed charge is collected at regular intervals with the rent, or otherwise, and a certain number of lamps of definite size could then be used without a meter by the consumer, who undertook to avoid wasteful use and not to increase the number or size of his lamps. The success of this method varied greatly, in some districts leading to waste and abuse and in others giving fair satisfaction. There appears to be no tendency for it to extend, the limitations of such supplies to lighting, and the ease with which electricity can be used over abnormal hours or for other purposes, making it unpopular with progressive suppliers, particularly when the supply is derived from coal. On hydro-electric systems the disadvantages are not so immediately apparent.

Even where "demand limiting" devices are used, abuse is not entirely checked, whilst progressive electrification is, and some of the conveniences of electricity have to be sacrificed, so marking the method down as a cheap or inferior supply in the minds of the users.

It may be argued that those who can buy only in small instalments and for cash can never buy well, but the total amount paid in the year by small householders for light and heat of all kinds is considerable and worth collecting, whilst the increase in comfort arising from the use of electricity is even greater in the homes of the poor than in those of the well-to-do.

RELATION BETWEEN ALTERNATIVE TARIFFS.

As in most cases the multi-part or subscription tariff is optional to the consumer and is alternative to flat rates, it is desirable that these flat rates should not be unduly low. The consumer seldom starts with an all-electric house but, under an encouraging tariff, progressively electrifies his home methods.

In some cases progress with good and simple multi-part tariffs has been hampered by too low a flat rate for lighting, with the result that the consumer has little incentive to change over unless he puts into use a considerable amount of electrical equipment. Very low lighting rates are seldom justified and may hamper progress by dissipating a surplus of revenue, which could better be employed in developing distribution and consumers' equipment facilities to enable a much wider use to be made of the supply. A commercially-minded management will remember that the value of electric lighting is always increasing, the demand is always for more light, and the tendency is to use it as a luxury and a decorative feature and not merely to regard electric light as a substitute for some other light.

LOAD LEVELLERS.

In the delivery of energy to many small users over an extensive area, minimum cost can only be reached when every user's demand is steady and continuous over all the hours of the year; in this case the distribution investment and other costs have the benefit of division by a load factor of 100 per cent. Failing this, a similar condition is approached where there is a high diversity in the times of use of energy as between one consumer and another, the increased load factor then applying to the generating plant and to a greater or less degree along the distribution network.

Where a fixed charge is made per kilowatt-year, as in the case of some hydro-electric supplies, there is a strong tendency for the consumer's load curve to approach in shape the desirable rectangle. Cases are even reported where the electricity supply secured under these conditions is treated by the consumer as a constant or "base load" of heat energy, extreme needs being met by the use of oil or other fuel, and this regular demand for electricity being achieved by alternatively switching it to lighting, water-heating, food-cooking or warming of the house.

Some attempts have been made in this country to effect the same object by interconnection of cooker elements, water heaters and lamps, so that any combination can be used, but not exceeding a certain capacity in watts at any time.

Recently, also, devices known as "load levellers" have been introduced to offer the same facilities automatically, storage water heaters being generally employed to take up in varying steps the difference between the kW demand allowed under the tariff and the actual demand at any time for light, power or cooking.

For the latter purposes the consumer's need must be met as it arises, whilst the heating of water under a storage system can be carried out, within limits, at any time during the night or day.

A fixed charge per kilowatt, or a limit to the number of kilowatts of demand, having been arranged, it is the duty of the load-levelling apparatus to switch on to or out of the heat-storage tanks such proportion of the demand agreed as is not, from time to time, being used for other purposes.

Similar in object is the system referred to as the "dispensable circuit." In this the heat storage is connected to a special circuit and the amount of energy it can consume is regulated by the use of all the other household appliances which are on the "indispensable circuit"; in practice the former endeavours so far as possible to fill in the gaps in demand produced in the latter, resulting in a consumer's load curve which approximates to a rectangle or the ideal 100 per cent load factor.

HEAT STORAGE.

The storage of electrical energy in the form of heat, viz. as hot water for use as such or for space heating, or as hot oil or refractory material for space heating, has made considerable progress already and offers great possibilities of increasing the load factor on plant and on local networks (often quite as important in reducing the cost of supply). Space heating of this class has, however, none of the advantages and attraction of the radiant electric fire, and although more suitable and efficient for certain situations and uses, by that reason finds itself in direct competition with low-temperature hot-water systems, i.e. is only possible on a large scale and at quite low rates for energy consumed.

INFLUENCE OF BULK-SUPPLY COSTS.

In recent times no less attention has been given to the important subject of power tariffs and, although outside the scope of this review, it must be remembered that consideration of power tariffs may have an increasing influence on the rates and charges for domestic supplies. Under the ægis of the Central Electricity Board the authorized distributors will buy or have their own supplies charged to them in bulk on a maximum demand tariff, a condition which may compel a closer inspection of the effect of new load on their overall load factor.

Although in some of the domestic applications there is a large diversity factor, short-period uses of electricity being spread over a long period of the day, yet some of the more important uses—cooking and water-heating, for example—are required by most people at the same time of the day as dictated by routine. The water-heating problem will probably be solved by heat storage and off-peak supplies. Space heating and room heating at rates low enough to compete with gas and coal may come to be used over long hours and so present no great difficulty, at least in urban areas, but as used to-day, mostly for occasional heating and as a supplement to fires, electric heating already presents problems of some difficulty to the tariff maker, providing on occasions a demand on the plant and distribution out of all proportion to the annual revenue resulting from it.

GENERAL CONSIDERATIONS.

The more extensive use of electricity in homes of all classes is a subject to which great attention has been given in recent years by all sections of the industry. In certain urban areas very great success has attended this phase of development and to-day the conditions for it are understood.

The wiring of buildings has been simplified, accessories and fittings have reached some degree of standardization, the apparatus for heating, cooking and labour-saving exists in great variety, of British make and reliable to a degree unknown a few years ago, whilst in the realm of lighting there is an entirely new and growing movement toward efficiency and beauty in a branch of electrical work which many regarded only a few years ago as capable of but little further advance.

The study of domestic electrification and the establishment of hire and hire-purchase methods to enable householders to enjoy the advantages of the cheaper electric power now available in most places has had the serious encouragement of the Electricity Commissioners* and has been fostered by the work of the British Electrical Development Association, the Electrical Association for Women and the great trade organizations promoting the interests of the makers of electrical plant and apparatus, cables and lamps, and also the wholesalers and contractors for installation work.

These efforts have awakened the public to the possibilities of electricity in their homes. A real demand exists and, if it is welcomed with a simple tariff and a commercial policy on the part of the authorities responsible for the distribution of electric power, the householders of this country may, in the course of a few years, consume as much electrical energy in a year as is at present supplied annually by all the statutory undertakings in this country.

The form in which tariffs and charges are presented to the public, and the conditions under which electricity is supplied or apparatus hired, should be as simple as is consistent with accuracy and the safety of the supplier.

The electrical industry has frequently been at fault in this respect, passing on to the uninstructed public in its printed forms the work of legal or technical minds, bristling with expressions which arouse suspicion, or decimals which are not understood. For success in this department of the supply industry the scientific or legal basis of the work needs to be concealed under the language and arithmetic which the housewife encounters in her business with the butcher and the baker.

---

* A Committee appointed by the Electricity Commissioners under Section 4 of the 1919 Act produced a report on method of charging for domestic supplies. This report is obtainable from H.M. Stationery Office and is of interest to students of this subject.

THE ELECTRICAL EQUIPMENT OF AUTOMOBILES.*

By Professor S. **Parker Smith**, D.Sc., Member.

The electrical equipment of the automobile has followed a course of progressive development from an accessory which, in the first instance, was added to the car after purchase, to its present position in which it forms an integral part of the equipment and is built into the chassis by the manufacturer. Electric ignition was the earliest application, and its adoption is now universal. Likewise electric lighting, bringing freedom from mess and smells, and the ability to light the lamps in a gale, gradually ousted the popular, and originally more powerful, acetylene lamp. With lighting, the battery was introduced, unless one was already installed for coil ignition. The next stage, namely the introduction of the charging dynamo, was inevitable; and, with the battery and dynamo installed, further applications became possible. The relatively large battery required to control the 3-brush dynamo assisted the application of the starting motor, now universal on most private vehicles and widely adopted on certain commercial types. The later introduction of other electrical accessories, such as the electric horn, windscreen wiper, fuel pump, signalling devices, etc., whether as extras or as part of the standard equipment, was both simple and natural.

† Institution of Automobile Engineers. ‡ British Standard Specification.

Almost without exception, every piece of electric equipment for automobiles had to be specially developed. This development was generally associated with strong competition from non-electrical alternatives, and a critical, if not hostile, attitude of car manufacturers towards electrical equipment. The competition between automobile makers was also keenly felt by electrical firms, though doubtless improved performance and reduced weight and cost were the response to many such difficulties.

As in most other industries, early progress produced a multitudinous variety of equipment and wiring diagrams. This stage of development now appears to be passing and signs of standardization are already apparent. Among certain British manufacturers determined attempts have been made to ensure interchangeability wherever possible. Table 1 shows the activities of the Society of Motor Manufacturers and Traders (S.M.M. and T.) and of the British Engineering Standards Association (B.E.S.A.) in this connection, while in Tables 2–10 data concerning batteries, cables, brushes and lamps are given. It is satisfactory to note that, in general, these specifications are well observed by many manufacturers, particularly in new designs.

---

* A review of progress. Reprints in pamphlet form, price 1s. each, can be obtained from the Secretary of the Institution.

In this review the progress of the several parts of the electrical equipment of automobiles is dealt with in the following order: Wiring systems; Batteries; Lighting; Charging dynamos; Starting motors; Dynamotors; Brushes; Miscellaneous; Ignition systems.

WIRING SYSTEMS.

Distinction must be made between the high-voltage ignition system and the low-voltage system used for all other electrical services.

Low-Voltage Systems.—Low-voltage wiring systems may have an insulated or an earth return, the earth part of the circuit being formed by the chassis. Two voltages have become standardized: 6 volts and 12 volts. The 6-volt system is almost universally employed on American cars, while the 12-volt system is mainly used in Europe. The 6-volt system is still met with on certain British cars, though generally only on earlier models. For the same percentage voltage-drop, four times as much copper is needed in the 6-volt as in the 12-volt system. This relation also exists between the insulated-return and the earth-return system. In 12-volt systems, the drop in the lighting cables is usually about 0·5 to 0·75 volt, and somewhat less in 6-volt systems. Omnibuses and lorries are mostly wired with an insulated return. The earth return is used more widely on private cars.

Types of Low-Voltage Automobile Cables.—Experience of automobile wiring soon revealed that ordinary protective compounded braiding over the vulcanized rubber lapped with a varnished cambric tape was not equal to the severe service demanded. Armouring was one of the means adopted to meet the requirements. American practice was to armour the cable with a spiral of galvanized mild steel. European practice favoured aluminium, though brass and nickel-silver helices were also used for armouring. Steel has a tendency to cut into the insulation, while after exposure aluminium tends to weaken and break away. A braided armouring of thin wire has also been used.

As an alternative to armouring, another development consists of a cellulose-varnished outer sheathing. The coating of cellulose varnish presents a bright, polished, smooth surface, usually left black, which will not crack when bent and serves as a protection against oil, petrol and water. This type of finish can be applied to any automobile flexible which has as its final protection a fine cotton braid. Startor cables are usually finished with a strong, stout braid heavily treated with a wax compound.

Another type of cable extensively used for the wiring of automobiles is the tough rubber sheathed (usually known as C.T.S.). The tough rubber filling and covering is not easily damaged; it is lasting and flexible, and greatly reduces the danger of earthing.

For further protection of cables, it is the practice of some makers to run the insulated conductors through flexible metal sleeves, which may be in different colours where desired.

Standard Lighting and Starting-Motor Cables.—Existing practice was largely standardized in B.S.S. No. 5002—1924. This standard specification for electric lighting and startor cables for automobiles recognizes the 6- and 12-volt systems with earth return and with insulated return. The types of covering specified are braided and compounded, armoured and C.T.S. The specification states that compounded braiding shall afford protection against water and oil, and the cable shall have a smooth flexible surface. Armouring is to be in the form of a close helix of metal of approximately half-round section not less than 0·015 in. thick. C.T.S. is to form a circular section. Lighting conductors shall be made up of tinned copper wires, 0·012 in. in diameter, and each conductor shall be insulated with vulcanized india-rubber not less than 0·025 in. thick. In a twin cable, the rubber shall be coloured red on one core and black on the other. In a triple cable, white shall be the colour of the smallest core. The S.M.M. and T. recommend that positive wires shall be red, negative wires black, and field wires green.

The B.E.S.A. sizes are given in Tables 2 to 4.

TABLE 2.

Lighting Cables with Insulated Return.

	Conductor	Maximum overall diameter	
		Braided and compounded, or armoured	C.T.S.
		in.	in.
Dynamo	2 × 35/·012 1 × 14/·012	0·38	0·4
Battery	2 × 35/·012	0·37	0·39

TABLE 3.

Lighting Cables with Earth Return.

	Conductor	Maximum overall diameter	
		Braided and compounded, or armoured	C.T.S.
		in.	in.
Dynamo	2 × 35/·012	0·37	0·39
Battery	1 × 35/·012	0·225	0·25
Lamp	1 × 14/·012	0·19	0·22

TABLE 4.

Starting-Motor Cables.

Conductor	Maximum overall diameter		
	Armoured	C.T.S.	Braided
	in.	in.	in.
37/·036	0·46	0·495	0·47
61/·036	0·545	0·58	0·555
61/·044	0·63	0·69	0·64

In some wiring systems all lighting and accessory cables are braided together, each conductor having a distinctive colour and being cut to the appropriate length.

The practice as regards fusing varies widely. One modern plan is to have a combined junction and fuse box of moulded material, each circuit being separately fused.

High-Voltage Cables.—All high-voltage systems have an earth return. Ignition cables are made of tinned copper wires, stranded and insulated with 1, 2, 3 or more thicknesses of rubber. The layer next the conductor is of pure rubber, the whole being vulcanized together to the required diameter. The strands are of Nos. 30 to 33 S.W.G. (about 0·01 in. diameter), the number varying up to 41. The overall diameter is made in sizes from 4 to 12 mm, the common size being 7-mm cable. For applying the rubber, two methods are in use: the longitudinal method in which the rubber is applied by means of grooved steel rolls, and the extrusion or forcing machine method.

As a further protection against deterioration from the effects of heat and oil, ignition cables can be braided and well treated with cellulose varnish. The varnish may be applied in distinctive colours to enable the cylinder connections to be readily traced.

Tough rubber sheathing also forms an admirable protection for high-voltage cables, and is now widely manufactured for this purpose.

For providing ready identification of the several wires, the S.M.M. and T. recommend the following colour code: No. 1, red; No. 2, yellow; No. 3, black; No. 4, green; No. 5, brown; No. 6, blue; No. 7, orange; No. 8, slate. This can be carried out by covering the cable with a cotton sleeve and impregnating with a baking varnish of the appropriate colour. The overall diameter of a 7-mm cable so treated should not exceed 8 mm.

BATTERIES.

Originally supplied for ignition purposes only, it may now be said that the battery is an essential part of practically every electrical device, except the magneto, at present used on automobiles. The earliest source of electricity on the car was a primary battery, soon to be followed by a lead-acid storage battery in a celluloid case. The number of cells was settled by the voltage, being 3 for the 6-volt system and 6 for the 12-volt system. An important influence on the size of the battery was the 3-brush charging dynamo, an ample battery being needed to anchor the voltage and to counteract to some extent the undesirable charging characteristics of the generator. The large capacity thus required proved invaluable for the starting motor, the severe demands of which led to the present mode of construction. In addition to the tax placed on the battery by the 3-brush dynamo and the starting motor, automobile batteries frequently suffer from neglect of topping-up and abuse from overcharging and over-discharging.

Construction.—In order to supply the very large current required at starting, the plate surface has to be made as large as possible. Thus the automobile cell is characterized by a large number of comparatively thin plates.

Rating.—The ampere-hour capacity of the battery is given either at the 10-hour or at the 20-hour discharge rate, the latter usually being somewhat higher, say 10 per cent, than the former. In addition, the discharge current is also given at the 5-minute rate, this current being about 30 times the current at the 10-hour rate, and is roughly the current taken by the starting motor on switching in.

Containers.—The celluloid container was replaced by separate 2-volt units in ebonite boxes placed in a wood case. Later the multi-compartment container moulded of ebonite or some synthetic composition was introduced, and the 1-piece moulded type with 3 or 6 compartments became standard practice. Each compartment is fitted with a moulded lid securely sealed at the edges, and is closed by a ventilated stopper or plug. The moulded container is made strong enough to render a crate unnecessary.

Mounting.—The battery is mounted on the running board or on the chassis, and secured by bolts or other arrangement.

TABLE 5.

Dimensions for Containers of Car Batteries.

Minimum capacity at 10-hour rate	Maximum overall dimensions				
	Length		Width	Height	
	6-volt unit	12-volt unit		Without lid	With lid
amp.-hours	in.	in.	in.	in.	in.
48	8½	13½	7½	9⅞	10¼
60	9½	16			
72	10½	18			
84	11½	21			
96	12½	24			

Plates.—In automobile cells the plates are ⅛ in. to 3/32 in. in thickness, the modern tendency being towards the substitution of 3/32 in. for ⅛ in. The separation between plates is reduced to a minimum. The height and width of the plates are frequently 4 15/16 in. by 5⅝ in. respectively; previously the height of 4 3/16 in. was more usual.

Separators.—These are necessary to prevent short-circuits due to buckling of the thin plates or dislodged paste. Different kinds of separators have been used, but wood separators are now almost universal. These are made in the usual grooved and ribbed design.

Dimensions.—For the guidance of makers and users, the maximum overall dimensions in Table 5 have been fixed to indicate the space to be left by the chassis maker. (For standard specification, see Table 1.)

Terminal Posts.—The terminal posts of startor and lighting batteries have been developed into the taper pattern with the following dimensions:—

Small diameter of negative post..	⅝ in.
Small diameter of positive post..	11/16 in.
Taper	1 in 9 on diameter
Minimum length of taper ..	11/16 in.

Cable Connectors.—The cable connectors for the battery are of brass, lead coated, the taper corresponding to the taper of the terminal posts. The clamp bolts for tightening the connectors are of mild steel, lead coated.

Density of Electrolyte.—In order to increase the capacity somewhat, it is usual to employ in automobile batteries stronger acid than in stationary batteries. The density of the electrolyte specified for filling varies from 1·25 to 1·3, the figure 1·28 being fairly common.

The chief differences between different makes are matters of detail, such as the means for securing the active material in the plates, prevention of internal short-circuit, anti-splash ventilation plugs, composition of the material of the container, etc.

Batteries for Commercial Vehicles.—For motor coaches and other large commercial vehicles larger batteries are often needed, though in some of these electric self-starting is not provided, or is only employed to move the engine sufficiently to draw an explosive mixture into the cylinders. For motor-omnibus lighting, the standard voltage is 12 volts and the capacity at the 10-hour rate of discharge may be 110 to 220 ampere-hours, the battery being made up in separate cells or in 6-volt units.

Alkaline Batteries.—Although, from a mechanical standpoint, the alkaline cell is well-suited to automobile work and is not damaged by heavy discharge current, the great obstacle to its use for starting automobiles has been its high internal resistance. Moreover, the relatively high cost of alkaline batteries has made competition with acid batteries difficult. Recently a nickel-cadmium cell has been developed in which efforts have been made to reduce the internal resistance. It is claimed that such a cell will discharge completely in 12 minutes at an average voltage of 1 volt, whereas under the same conditions an ordinary nickel-iron cell would give an average of only 0·5 volt. The 60-ampere-hour battery is able to maintain 200 amperes for 12 minutes; while it is stated that a 120-ampere-hour battery, designed for commercial vehicles, will give an initial kick of 500–600 amperes. With the reduced internal resistance it is therefore possible to employ alkaline batteries for starting. Alkaline batteries are making rapid headway for use with omnibuses, a common installation being 10 cells of 180 ampere-hour capacity at the 10-hour rate. A partial offset against their high initial cost is the long period for which they are guaranteed by the makers.

LIGHTING.

Experiments with electric lighting for automobiles date back to the early years of this century, when not only were the available carbon filaments too fragile and the batteries too undeveloped for road conditions, but a suitable mode of controlling the charging dynamo was lacking. The introduction of the metal-filament lamp was a marked advance, and later the gas-filled bulb provided an economical means of obtaining the requisite illumination for night driving at high speeds. Unfortunately, the progress made in solving one problem introduced another, namely, that of glare. The modern tendency is to use only gas-filled lamps for headlights, and vacuum lamps for the side, tail and dash lights. The lamp load may vary from about 40 watts on a small car to about 600 watts on an omnibus.

Headlights.—The present practice is to use parabolic silvered and varnished reflectors with the filament of the bulb at the focal point. British makers show a marked preference for the linear or straight-helical filament with the axis of the filament along the centre of the reflector [see Fig. 1 (*a*)], in contradistinction to the V-shaped filament with the apex at the focal point as favoured on the Continent [see Fig 1 (*b*)]. Accuracy of reflector shape is important to prevent focal variation in the beam intensity giving rise to streaks and patches. A frosted cover glass in front of the headlamp, giving a slight amount of diffusion, is commonly used to eliminate streakiness.

Glare.—Innumerable patents have been taken out with the object of obtaining adequate driving light with freedom from dazzle to oncoming traffic, but it is now generally recognized that any beam which will give a long range of illumination must produce dazzle to anyone meeting it. The present tendency is to use a normal driving beam which covers a fair vertical range in order to allow for variations in the trim of the car or contour of the road, and to provide means for depressing the beam when meeting oncoming vehicles. This depression can be obtained mechanically by tipping the reflector or the headlamp as a whole, or electrically by using two bulbs, or two filaments in one bulb, for producing a normal and a depressed beam respectively. In addition to depressing the beam, it is common practice to swing it slightly to the left to illuminate the near side of the road.

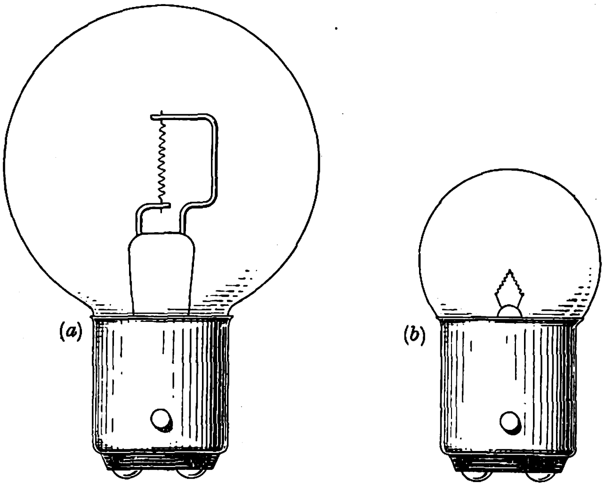

FIG. 1.—Automobile bulbs.

(*a*) Linear filament. (*b*) V-shaped filament.

Voltage Variation.—The voltage of a lead-acid cell may vary from 1·8 to 2·7 volts, and it is usual for the charging dynamo to be switched on when the lamps are in use. In order to prevent the lamp voltage becoming excessive, the dynamo voltage is usually adjusted so that with the headlights switched on the battery floats on the busbars. In this condition the lamp voltage is practically the open-circuit voltage of the battery. When the headlights are switched off, the battery will then take a charging current, so that the voltage may rise to 2·7 volts per cell. For the side and tail lamps, therefore, where a high efficiency is not demanded, it is common practice to supply bulbs of higher nominal voltage.

Standardization of Automobile Bulbs.—Electric lamps when used in the automobile industry are generally referred to as "bulbs." In 1923, the manufacturers of electric bulbs and of car-lighting equipments discussed the possibility of reducing the large variety of bulb types then in use. It was agreed that in future 10 definite types of bulbs would cover normal requirements, and a specification was drawn up by the Society of Motor Manufacturers and Traders and the Electric Lamp Manufacturers' Association of Great Britain. This specification was revised in 1929, and the I.A.E. Data Sheet No. 104R was issued, in which vacuum-type headlamp bulbs were deleted, leaving the 7 types shown in Table 6. The chief points are:—

TABLE 6.

Standard Automobile Bulbs.

Type	B.A.S. No.	Fig. No.	Rating		Initial rated efficiency *	Initial luminous flux †
			watts	volts	lumens/watt	lumens
Headlights (gas-filled)	1	1 (*a*)	12	6	14	168
	2		18	6	15	270
	3		24	12	16	384
	4		36	12	17	612
Side, tail and dash lights (vacuum) ..	8	1 (*b*)	3	6	7·5	22·5
	9		6	6	8·0	48
	10		6	12	8·5	51

* Tolerance ± 15 per cent. † Tolerance ± 20 per cent.

Types of lamp: Headlights (gas-filled); side, tail and dash lights (vacuum).

Standard voltages: 6 and 12 volts.

Rating: See Table 6.

Dimensions: The overall dimensions of bulbs, caps and holders are specified for the several bulbs.

Filament: Tungsten, disposed symmetrically in bulb, and supported to burn satisfactorily with lamp at any angle. To be uniform in appearance both at rated and at half rated voltage.

Cap: Straight-sided, of either of the following types:
(*a*) Small bayonet, double-contact cap.
(*b*) Small bayonet, centre-contact cap.

About 80 per cent of the orders for British bulbs are now for standard types. The automobile industry has also been experimenting with other types of bulbs, such as coloured bulbs, double-filament bulbs, etc., with a view to increasing their illuminating effect while diminishing glare.

CHARGING DYNAMOS.

The problem with the car-lighting dynamo was the same as with the train-lighting dynamo, and arose from the wide range of speed over which it was required to generate a constant voltage. In the earliest types a belt drive was common, no special provision being made for mounting or driving the generator. Many devices for obtaining constant dynamo speed were tried and discarded, along with other mechanically- and magnetically-operated contrivances for regulating the output. Ultimately the so-called "constant-current" type of dynamo ousted most of its rivals, until in its turn it has now to compete with the constant-voltage type.

Originally 2-pole machines were tried, often with only one pole wound, the eccentricity being used as a means of adjusting belt tension. The 4-pole type was soon found to be more economical in material and is now nearly universal. The shell is cylindrical, being made of mild-steel tubing or bent sheet with butt-welded ends.

In practically all modern equipments a reverse-current relay is employed as an automatic cut-out to isolate the generator from the busbars as soon as its voltage, owing to drop in speed, falls below a predetermined value, and to switch it into circuit when its voltage rises above a predetermined value. With many equipments a field switch mounted on the dash is supplied in order to enable the driver to switch the dynamo in and out of action.

The dynamo is usually positively driven by the engine, the speed ratio depending on circumstances. Common dynamo speeds are 1 to 1½ times engine speed. The output may vary from about 50 watts, requiring a machine with an outside diameter of some 3½ in., for a small car, to about 720 watts for an omnibus, the dynamo having an overall diameter of 8 in. and weighing about 120 lb.

Where coil ignition is used, it is a common practice to drive the ignition head from the end of the dynamo. In future, the dynamo may be relieved of this unwelcome burden. The two standard methods of mounting are by means of a cradle and straps and by means of a flange. In Table 1 reference is made to the specifications of standard dimensions adopted for both these arrangements.

Constant-Current Dynamo.—Regulation is here obtained by means of armature reaction, which distorts the flux and reduces its effective value as the current increases. To anchor the voltage a battery is needed, and with this combination it is possible to maintain a fairly constant current over a wide range of speed. In one arrangement a portion of the armature winding is short-circuited, but the rather large additional brushes tend to limit the application of the method to 2-pole machines and, consequently, its usefulness to motor-cycle work. The 3-brush dynamo, in which the field is excited from a main brush and a third or control brush, is the common solution, and this method of regulation is probably the one now most widely used in this country. Not only must a battery of ample capacity be employed to control the voltage, but the characteristic of the dynamo is the opposite to that required by the battery, namely a falling charging current with a rising voltage. To prevent excessive overcharging, a dynamo field-switch becomes essential. This sometimes takes the form of a 2-position switch for full- and half-charge; in the latter position a resistance is inserted in the field circuit to reduce the charging rate. The operation may be manual or automatic, the latter being favoured in many cases where coil ignition is employed. Correct charging rates, however, are difficult to obtain.

TABLE 7.

Cylindrical Brushes for Magnetos [see Fig. 2 (a)].

No.	Nominal diameter	Overall length	Head and neck				Groove (if required)	
	A	*B*	*C*	*D*	*E*	*F*	*G*	*H*
	mm	mm	mm	mm	mm	mm	mm	mm
1C, 2C, 3C..	4	10, 13, 16	3·0	2·4	2·5	0·5	0·75	0·38
4C, 5C, 6C, 7C	5	10, 13, 16, 19	4·0	3·4	3·2	0·5	0·75	0·38
8C, 9C, 10C, 11C, 12C	6	10, 13, 16, 19, 27	4·5	3·9	3·5	0·5	0·75	0·38
13C	7	10	5·0	4·2	4·0	0·7	1·00	0·50

Constant-Voltage Dynamo.—This represents a further step towards making the operation of the charging set independent of the driver. Here a quick-acting field regulator, similar in principle to the Tirrill regulator, is used to control the voltage of a plain shunt-wound machine. With this device the dynamo can be used without the battery. Furthermore, the maximum charging rate occurs when the battery is in a discharged state, and falls off as the battery voltage rises. The sensitive part of this system is the contact points, but pitting and welding have now been practically overcome. This method is employed almost universally in Germany, but in Great Britain its use is mainly confined to commercial vehicles.

STARTING MOTORS.

The plain starting motor is usually a 4-pole series motor of relatively small diameter and considerable length. The problem here has been the transmission from the motor to the engine. Practically all forms of free-wheel and other drives have now given way to the so-called "Bendix drive," or its equivalent. This merely consists of a loose pinion running freely on a screwed quill and engaging with a toothed ring on the engine flywheel. The engagement and disengagement are automatic. The problem is to provide a combination which will exert sufficient breakaway torque under the worst conditions and will also bring up the speed to a sufficient value to cause the engine to fire. A gear-ratio of about 10 : 1 or 12 : 1 is usually adopted. The overall diameter of the motor varies from about 3½ in. with a breakaway torque of 5 lb.-ft. to about 6 in. with 40 lb.-ft., the latter being suitable for starting omnibus engines.

The motor is generally attached to the flywheel housing by means of a flange on the end-plate. (For standard specification, see Table 1.)

DYNAMOTORS.

Early attempts were made to combine the charging dynamo and the starting motor into a single unit. The compromise is a poor one both electrically and mechanically, but it enables two machines to be replaced by one. If the combined unit, commonly known as a dynamotor, is permanently geared to the engine, it is not feasible to have a gear-ratio greater than about 3 : 1 owing to speed limitations; on the other hand, in order to provide sufficient breakaway torque with a low gear-ratio a large machine is necessary. With higher gear-ratios, say 7 : 1, it is usual to employ gearing which engages automatically when the machine functions as a motor; when running normally as a generator the machine is driven at engine speed. Mountings for dynamotors have also been standardized (see reference, Table 1).

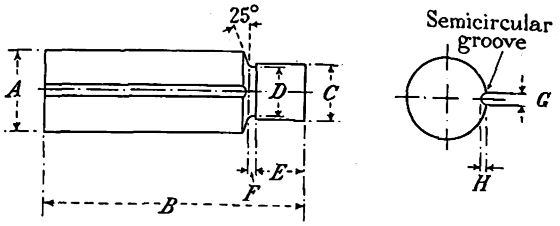

FIG. 2 (*a*).—Cylindrical magneto brush.

BRUSHES.

Carbon brushes have been developed to meet the needs of the various electrical machines used on automobiles. At present the variety of such brushes is very great, but attempts are now being made to conform to the standards which have been adopted by the S.M.M. and T. and the B.E.S.A.

Magneto Brushes.—The magneto with revolving armature needs two brushes to convey the high-voltage current from the slip-ring to the revolving distributor arm, also two low-voltage brushes—one for earthing the magneto windings and the other for short-circuiting the primary at the ignition switch. With stationary windings, the only essential brush is the one for conveying the current to the revolving distributor arm. Where a contact-type distributor is used a further brush is required, and this presents the chief problem, for a soft and graphic brush causes tracking, while too hard a brush produces scoring. Non-graphitic, smooth carbon brushes are used throughout on ignition apparatus, though on brass slip-rings electro-graphic brushes are occasionally employed. Standard dimensions of carbon brushes for magnetos are given in Tables 7 and 8 and Fig. 2 (for references, see Table 1). Fig. 2 (*c*) shows the dimensions of the earthing brush on the contact breaker.

Dynamo Brushes.—Owing to the high current densities now used—60 to 70 and even 90 amps. per sq. in.—carbon brushes have been replaced by electro-graphitic brushes. Natural graphite is occasionally used to reduce noise and costs. The control or third brush is often of hard carbon because of its cleaning properties, but brushes with higher graphitic content than the main

FIG. 3.—Brushes for 3-brush dynamos.

brushes can also be used without sparking troubles. The output of the 3-brush dynamo is very sensitive to the bedding of the control brush, which should be perfect. Pressures of 4 to 5 lb. per sq. in. are employed, and higher pressures with very high current densities. The common type of holder used in this country is the box or slide type, and it is for this type that sizes have been standardized. In America the grip-type holder is fairly common.

In Table 9 and Fig. 3 the standard dimensions for brushes for 3-brush dynamos are given (for references, see Table 1).

Flexibles and terminal tags have also been standardized for dynamo and starting-motor brushes (see Table 1).

Starting-Motor Brushes.—Generally speaking, the starting motor is only in circuit when actually starting the engine. The density under the brushes at the instant of switching in may reach 2 000 amps. per sq. in., while 1 200 to 1 700 are figures frequently met with. Low contact drop, especially with 6-volt sets, here becomes all-important, and a copper brush with a very small percentage of graphite is used. For 12-volt systems, a grade with about 75 per cent copper is employed. In this connection, too, the pressure is all-important, the contact drop falling rapidly until about 8 to 10 lb. per sq. in. is reached. These high pressures are common for starting-motor brushes.

FIG. 4.—Brushes for starting motors.

In Table 10 and Fig. 4 the standard dimensions for starting-motor brushes with slide-type holders are given (for references, see Table 1).

Dynamotor Brushes.—The brush most favoured on dynamotors is a copper-graphite grade containing about 65 per cent of copper. This brush has a low contact drop and runs well at generator loads. The pressure employed is 5 to 6 lb. per sq. in. and the current density at the instant of starting is usually about 1 200 amps. per sq. in. The third brush is generally of hard carbon.

In general, it would seem that the progress in brushes has kept pace with the development of automobile equipment.

MISCELLANEOUS.

Probably all the foregoing can be regarded as essential parts of the equipment of a modern automobile, with the exception, perhaps, of the startor, which is not always fitted to commercial vehicles. There are in addition a number of other current-consuming devices, many of which can certainly be regarded as desirable, even if not essential. Some of these appliances form part of the standard equipment of various makes of auto-vehicles.

Electric Horns may be of the solenoid type where the diaphragm is actuated by electromagnetic action, or of the motor-driven type where a star wheel strikes a metal pin fixed to a steel diaphragm.

Windscreen Wipers are electrically operated by a small motor through reduction gearing. The motors are either of the series-wound type or the attraction type in which the revolving element carries no winding.

Signalling Devices including a rear "stop" light consisting of a red lamp and an illuminated signal usually operated by the foot brake, and direction indicators often controlled from the steering wheel.

Fuel Pump to replace an automatic vacuum chamber and operated by a solenoid.

Solenoids are also employed for the automatic operation of other devices.

Petrol Gauges and Cigarette Lighters are further instances of electric devices. For appliances such as foot or rug warmers for use in cold weather a socket is provided.

Assembly of Equipment on Chassis.—Originally no provision was made for electric wiring or equipment, but in modern practice these are supplied with and mounted on the chassis. Likewise the instrument board is carried on the chassis independently of the body. It is also becoming general practice to mount all instruments such as clock, oil gauge, speedometer, ammeter, etc., on a facia board, usually of metal and arranged for interior illumination. The position of the controls and switches has not been standardized, but there is a tendency to arrange those used in normal driving, such as horn, headlights, dipping device and direction indicators, near to or on the steering column.

Present-Day Tendencies.—It is recognized that in many directions further simplification and standardization are desirable and possible. Many existing differences are unnecessary and hinder standard manufacture. Progress has already been made towards standard dimensions, as indicated in Table 1, and, with the further elimination of special sizes and ratings, manufacturing costs will fall. It is recognized that many of the special features favoured by various manufacturers are not improvements, while they certainly add to the burden of the electrical manufacturer, the garage engineer and the user.

IGNITION SYSTEMS.

The introduction of electric ignition dates back to the pioneer days of the automobile. Despite the troubles associated with the induction coil and trembler, actuated at first by a dry battery, and the complication of a coil for each cylinder, it was soon recognized that more accurate timing was possible with the electric than with any other system of ignition. With the development of the magneto in Germany, the various systems of coil ignition in this country almost went out of use, though in America the coil retained its stronghold. As a result, at the outbreak of the War the ignition industry of Great Britain had passed largely into German hands, only one or two British firms maintaining a small output of magnetos.

The advent of the War gave a great impetus to the manufacture of British magnetos for road, air and water transport, and since that time much of the development of magnetos has taken place in this country. Extensive research was necessary to keep pace with the growing demands of the petrol engine—higher speeds, larger compression ratios and greater numbers of cylinders—and to meet the active competition of coil ignition.

Detail Development.—With the introduction of the high-voltage distributor, permitting the use of a single ignition device with any number of cylinders, and the contact-breaker, ensuring precise timing of the spark, development became chiefly concerned with design details and materials of construction. Most of the early work was done on the revolving-armature magneto fitted with a horseshoe permanent magnet and a shuttle armature. The substitution of laminated for solid pole-shoes assisted starting by producing better low-speed performance with retarded spark. Mechanical rigidity was greatly improved by the construction of the base and the two end-plates as a single casting. In addition to the carbon-brush contact-type distributor, the gap type has also been developed. Nickel segments with a revolving nickel electrode are the chief features of the latter construction. Ventilation is necessary in order to remove the effects of ionization due to the spark. The rotary safety spark-gap is also used to reduce ionization. The original design of condenser, in which the mica and foil laminæ were assembled by punching or drilling holes and riveting into a block, has been superseded by designs in which the laminæ are securely clamped mechanically without any form of riveting. Several successful designs, with an increased factor of safety and reduced risk of cracking starting at the rivet holes, have been developed. Paper condensers have replaced mica condensers in certain magnetos with stationary windings and those used for motor cycles.

Moulded insulation materials for ignition appliances show remarkable progress. A moulded material was needed which would withstand the action of oxides of nitrogen produced by brush discharge and ionization. Many of the earlier hard-rubber compounds produced deliquescent nitrates and gave rise to surface leakage, especially in damp weather. The mouldings now employed can be divided into rubber-base and synthetic-resin-base materials. The former are composed of rubber and sulphur with a filling material to give body and rigidity to the vulcanized rubber, while the latter belong to the synthetic-resin class which is now finding so many uses in electrical and other work. Each class has its own sphere of application; for example, the brush track in the distributor requires a rubber-base material, and with the elimination of unsuitable ingredients the earlier troubles have been overcome. Synthetic-resin products have revolutionized the cheap and accurate manufacture of moulded materials for ignition apparatus.

The material employed for the contact points until recent years was an alloy consisting of 25 per cent iridium and 75 per cent platinum. The successful development of tungsten contacts has enabled the costly precious metals to be dispensed with for this purpose. With tungsten contact points the current must not exceed about 4 amps. nor the primary voltage at break about 280 volts, which limits the number of primary turns.

The insulating materials employed in ignition devices and their mode of application have been greatly improved. The load on an ignition device consists of a series of high-frequency surges with each spark, necessitating reinforcement of the end layers and careful insulation throughout the windings to prevent progressive breakdown. The satisfactory enamelling of very thin copper wire—about 0·004 in. in diameter with an enamel coating of 0·0005 in.—and the use of special varnished silk have enabled makers to produce satisfactory high-voltage windings occupying such small space and frequently subjected to centrifugal force.

TABLE 11.

Properties of Permanent-Magnet Steels.

Steel	Coercive force	Remanent flux-density	$(BH)_{max.}$
35 % cobalt ..	238	8 900	910 000
15 % cobalt ..	186	8 500	615 000
9 % cobalt ..	148	8 200	455 000
6 % tungsten .	62	10 000	287 000
2 % chromium	59	9 700	245 000

Permanent-magnet steel has shown remarkable development. Previously a 6 per cent tungsten steel was used for magnetos in this country, and a 2 per cent chromium steel in America, but the introduction in 1920 of cobalt steel, with its high coercive force, permitted a correspondingly small volume of steel to be used for a given output or energy storage. Representing the volume of steel in a magnet by AL (area × length) we have:—

$$AL = \frac{B}{B}A \times \frac{H}{H}L = \frac{(\text{flux} \times \text{magnetomotive force})}{BH}$$

The volume will thus be a minimum when BH is a maximum. This condition holds for maximum energy storage as well as for maximum output. Table 11 shows the improvement obtained in the value of $(BH)_{max.}$ by the introduction of cobalt alloys.

It is thus seen that with 35 per cent cobalt steel only one-third of the weight of material required with 6 per cent tungsten steel is needed. The cost of cobalt is its chief drawback. By its use, not only can the horseshoe shape be replaced by much shorter magnets, but such types of construction as the revolving-magnet magneto, otherwise impossible in the restricted space, become feasible. While cobalt steel was originally produced in rolled sections only, and earlier magnets were straight, or slightly bent, short lengths of steel, it is now possible to obtain 35 per cent cobalt-steel castings with coercive forces as high as 280 and $(BH)_{max.} = 1\,000\,000$. Experience shows that the ageing qualities of cobalt steel are at least as good as those of the earlier steels.

Later Types of Magneto.—Following the earlier type of magneto with revolving armature and stationary magnet, makers have developed types with windings and contact-breaker stationary. The polar-inductor magneto belongs to this class, the revolving part consisting of soft-iron inductors, while the magnets are also stationary. The revolving-magnet type, on the other hand, has a 2- or 4-pole cobalt-steel magnet. In both these types it is possible to obtain 4 sparks per revolution, compared with 2 sparks per revolution with the revolving-armature type. These newer magnetos, therefore, not only have the virtue of stationary windings and contact-breaker, but the speed of the 4-spark magneto is half that of the 2-spark magneto. This reduction in speed has enabled the magneto to keep pace with developments in the petrol engine, the 4-spark machines being widely used on engines with 6 or more cylinders. Cobalt steel is used on most of the later designs and also by some makers on the older type. (For references to standard parts of magnetos, see Table 1.)

Impulse Startors.—Where starting conditions are severe, as on large engines, trouble may arise with magneto ignition owing to the difficulty of rotating the engine at a speed sufficient to produce a spark with the lever fully retarded. Some improvement in low-speed performance is obtained by using a larger magneto, but auxiliary devices, such as the impulse startor, are now available. The impulse startor consists of two members linked together by a strong spring; one member is fixed to the driving shaft and the other to the magneto shaft, which is prevented from turning until the wound-up spring is released and gives a sudden forward impulse to the magneto, thereby producing the requisite spark. As the engine speed is increased, the impulse startor automatically falls out of action. I.A.E. Data Sheet No. 124 refers to impulse startor couplings.

Coil Development.—Many of the above progress details apply equally to the coil and the magneto. The cheapness of its construction, the simplicity of its drive and the ease of starting have enabled the coil to oust the magneto in many cases, and there are now probably as many makes of automobiles in Great Britain with coil as with magneto ignition. Most coils are provided with a straight core of iron laminations or wire, which leads to a very simple construction. The coil is usually mounted apart from the distributor and contact-breaker. The primary current is kept within the limit imposed by the contact points by the resistance of the primary circuit, and, in order to reduce heating in the coil itself, a large part of this resistance takes the form of a resistor external to the coil. By making this resistance of wire with a high temperature coefficient, an automatic means is provided of reducing the current from the battery when the switch happens to be left " on " and the contacts are closed with the engine at rest. In this way the safety of the coil is ensured and the rate of battery discharge diminished; also the fall in current at high speeds is reduced. Unlike the magneto, the coil functions best at low speeds, but difficulties may occur at high speeds with a large number of cylinders, for the contact period may then be too small to allow the current to attain a sufficient value to produce a spark. With 8 or more cylinders this difficulty may become pronounced, and some makers overcome it by using two distributors or by some equivalent device.

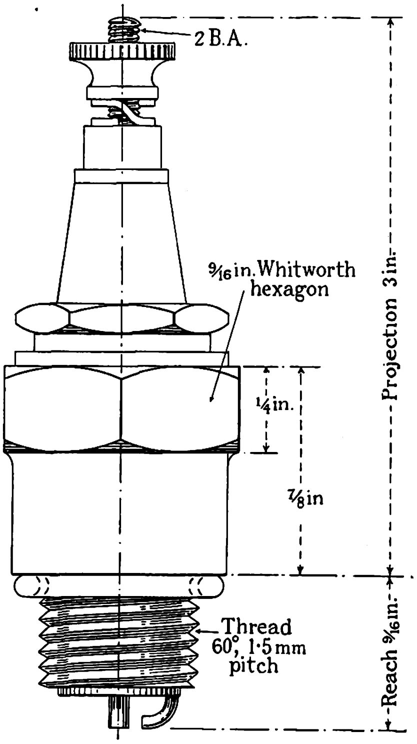

FIG. 5.—Standard dimensions of sparking plug.

Although there appears to be a tendency for both magneto and coil ignition to find their most suitable spheres of application, the outlook is not clear. It is possible that the revolving magnet will replace the revolving armature: this may influence future development. The coil as we now know it is largely an American development, but the problems peculiar to European practice, notably due to higher engine speeds, may also affect its future.

Dual Ignition Systems.—Only in a limited number of high-class vehicles are the two types of ignition combined, mainly with the object of securing greater reliability and easy starting. Various systems are in use, ranging from completely independent equipment with two sets of plugs to devices where a change-over switch controls a common distributor and contact-breaker, or the magneto winding is simply made to act as a transformer fed from the battery to facilitate starting. The fact that dual ignition is usually regarded as unnecessary may be taken as an indication of the high factor of safety attained by both the modern magneto and coil.

Automatic Ignition Timing Devices.—From time to time attempts have been made to simplify the driving of auto-vehicles by eliminating the need for manual control of ignition. The idea of fixed ignition was found to be unsatisfactory. The problem is to compensate both for throttle opening and for speed. Devices have been developed for dealing with both these variables, but they are usually too complicated for general application. It is possible, however, to design very simple devices based on centrifugal action to compensate for speed changes. With these devices fitted external to the ignition device proper, the ignition lever can be left in the fully advanced position, so that the optimum spark position of the magneto is not upset at starting or at low speeds. The hand lever can then be used for altering the timing as required by throttle opening. Ignition timing devices to compensate for speed changes are now a standard part of many equipments. Apart from convenience, their use leads to appreciable economy in heavy commercial vehicles.

Sparking Plugs.—The main dimensions of sparking plugs have been standardized for some years and the revised specification has been issued as B.S.S. No. 45—1928. The leading standard dimensions are reproduced in Fig. 5.

There is now a great variety of sparking plugs on the market, both of the porcelain and the mica type. The chief differences in detail have been made to keep pace with the increasing requirements of the engine. On the one hand the electrodes must be hot in order to burn off any oil or carbon deposit and to keep the plug voltage low; and on the other hand they must not be hot enough to cause pre-ignition. These requirements largely account for the difference in the design between a plug, say, for a racing engine and a plug for a touring engine. While, therefore, with the improved materials now used, the several types of mica and porcelain plugs have been made thoroughly reliable, their satisfactory use depends on correct application and gap adjustment. Owing to the wide range of service for which engines are designed, and to the diversity of cooling conditions to which a plug is exposed, a universal sparking plug seems at present to be an unattainable ideal.

CONCLUSION.

So many firms have generously supplied information for this review that it would be invidious to mention any by name; it must suffice to say that their aid was not only invaluable, but indispensable. To Mr. E. A. Watson and Mr. W. H. Glaser the author wishes to express his gratitude for the pains they have taken in criticizing the manuscript.

ELECTRIC TRACTION.*

By Lieut.-Col. F. A. CORTEZ LEIGH, T.D., R.E.T. (Ret.), Member, and M. G. SAY, Ph.D., M.Sc., Associate Member.

In the review published in the *Journal* in January 1927 (vol. 65, p. 143), Mr. F. Lydall gave a comprehensive account of the technical and statistical developments that had taken place up to that time. Consequently the present review will be confined principally to the events of the last three years.

Although there has been an awakened interest in railway electrification at home, attention must, nevertheless, be directed in addition to countries outside Britain, where many important suburban and main-line railways are electrically operated. Progress has been made in the engineering science of electric traction, brief details of which are given below.

(1) TECHNICAL.

The three years under review have been remarkable in the more highly developed countries for the intensification of road competition with tramways and railways by vehicles propelled by internal-combustion engines. In some cases, particularly with tramway systems having extensive interurban routes, the rail system has succumbed to the petrol omnibus; elsewhere, competition has resulted in a general speeding-up of traffic, with modernization of vehicles and increase of motive-power ratings. Certain railway systems have augmented their traffic by electrification, and on branch lines some success has been realized with petrol or oil electric rail-cars, incorporating a form of transmission that has been applied also to locomotives, especially in North America.

(*a*) INTERNAL-COMBUSTION ELECTRIC VEHICLES.

The internal-combustion electric vehicle comprises a prime mover, using either petrol or oil as fuel, driving a d.c. generator connected with normal series traction motors carried on the bogies in a manner similar to that employed in ordinary electric locomotives or motor-coaches. The high cost of petrol has been an obstacle in the development of petrol-electric vehicles in large units, and the design of Diesel engines has received corresponding encouragement. The advantages of the internal-combustion electric vehicle include without the necessity for contact-line gear and substations those of the electric drive, the elimination of smoke, noise and terminal delays, and economy of fuel. Although the Diesel engine possesses but small overload capacity, it has the ability, when combined with the electric drive, of supplying its full rating at any desired locomotive speed. Solid-injection engines are preferred, as their use renders air compressors and scavenging equipment unnecessary. A disadvantage of the Diesel-electric locomotive at present is its excessive weight, reaching 400 lb. per horse-power. The tendency of current design is to increase engine speeds. Piston velocities up to 1 250 ft. per min. at 600–1 000 revs. per min. are possible. The cooling difficulties are considerable with large units, since much heat must be conveyed away from the cylinder walls. Additional cooler-tenders have been found necessary in Russia.

The methods of control available include either constant or variable engine speed, combined with series-parallel connection and field weakening of the driving motors, and voltage control of the main generator, the field of which is usually supplied from a separate exciter. By providing the main generator with a differential compound field-winding, the output can be made approximately constant over a wide current-range.

A number of locomotives and rail-cars employing internal-combustion engines with electric drive are in operation in Canada, the United States and Russia. In Britain, the London, Midland and Scottish Railway have experimented with both a petrol-electric and a Diesel-electric motor-car.

(*b*) ELECTRIC LOCOMOTIVES.

The design of electric locomotives is proceeding in the direction of the elimination of side-rod drives. In the early days the application of electricity to train haulage presented problems in locomotive design which were solved by the direct use of the existing steam-locomotive mechanism. Subsequent experience showed that, if a rotating energy source were available, it was disadvantageous to convert it to reciprocation and back to rotation at the driving wheels. The electric side-rod drive was found to differ seriously from its steam prototype in that there was nothing corresponding to the cushioning action of the steam and sliding piston to take up play between the spring-borne motors and the driving axles. The consequent tendency to destructive vibration has resulted in maintenance costs rather higher than those necessary with individual-axle drives, which are therefore coming into still greater favour. It would, in fact, appear that the side-rod drive is obsolescent, at least for normal-gauge express locomotives. Several years of experience have amply demonstrated that individual-axle drives give a utilization of the available adhesive weight at least as good as that of coupled drives, so long as the motors are not connected in series. The side-rod drive persists, however, on the 3-phase zone in Italy. In the older locomotives, the transmission between the motor crank-shafts and the driving wheels comprised flat triangulated coupling frames, in the guide-bars of which the crank-pin of the central driving axle moved in a die block. The upkeep of this form of mechanism was found to be expensive, on account of the copious supply of oil demanded to keep the moving parts adequately lubricated. The more recent locomotives have therefore been provided with a 3-rod drive having a straight-line motion, eliminating the die block and guide-bars.

---

* A review of progress. Reprints in pamphlet form, price 1s. each, can be obtained from the Secretary of the Institution.

The Buchli drive is used extensively in Switzerland and Central Europe, and the Westinghouse geared quill mechanism has been supplemented by the Oerlikon link-work drive; all these are for express service. A more recent design introduced in Europe utilizes motors with vertical shafts, arranged in pairs, driving a common axle by means of quill-mounted bevel gears. Advantages claimed include a comparative absence of space restriction, easier maintenance, and a high centre of gravity. The quill gear, with its linkwork connecting with the driving axle, runs in an oil bath, greatly reducing the wear.

Some development has been observable on single-phase railways by the introduction of motor-generator conversion. The single-phase to 3-phase system is well known, having been in successful service on the Norfolk and Western and the Virginian Railways in America, the special advantage being the possibility of automatic regenerative braking. More recently, however, a single-phase synchronous motor driving a d.c. generator has been used, so permitting the employment of standard d.c. series railway motors, economical control and fairly simple regeneration. Locomotives embodying this system are in use on the new Cascade Tunnel electrification of the Great Northern Railway (U.S.A.). The synchronous motor is started as an induction machine with the assistance of the main d.c. generator running as a motor from a secondary battery. By over-exciting the synchronous machine a high or leading power factor is obtainable, compensating to some extent for line drop.

The use of regenerative braking continues to be confined principally to those lines on which there is a definite operating need for it, and in these cases there may be some sacrifice of speed control in order to obtain a convenient and safe method of recuperation. Thus the use of motor-generator or split-phase locomotives, mentioned above, enables regeneration to be obtained in a simpler manner than is at present possible when no such auxiliary equipment is provided.

Single-phase motors, which are now solely of the series type, are constructed either with or without resistors in the connections between armature coils and commutator. This reflects on the design, since a greater flux per pole can be allowed when resistors are used, but a greater axial length is needed and a certain amount of difficulty is introduced in the armature construction. The tendency is to use as large a number of poles as can be economically accommodated, since this increases the ratio of normal to synchronous speed—a condition favouring good commutation. In a recent design for a large motor it was found possible to dispense even with the neutralizing winding, with consequent gain in the permeance of the magnetic circuit. Any increase in the number of poles, however, necessitates the provision of a like number of commutator brush-spindles.

Nose-suspension-drive motors on d.c. lines do not show marked advances. The single-turn coil and the lap winding are being employed for high-voltage motors, and 6 poles used instead of 4 for the larger outputs. Forced cooling is almost universal, and box frames with roller bearings are in general use. For spring-borne individual-axle drives the twin motor is popular, embodying in one housing a pair of armatures. The advantage of high peripheral speed is obtained, but the number of bearings, commutators and brushes is, of course, doubled.

Three-phase motors are largely confined to the Italian State Railways. The pre-war construction with hollow motor shaft and with slip-rings on the main crank extension is now abandoned. The slip-rings are placed within the rotor core to save space, an arrangement successfully made despite the multiplicity of rings required where pole-changing is used for speed control.

A subject of growing importance in Europe where extensive main-line electric traction is concerned, is that of train-heating, which represents an appreciable proportion of the cost of running. Especially is this true of international trains and of through trains from steam-operated zones. The majority of these are equipped for steam-heating, and in consequence separate coke, coal or electrically heated boilers have been tried when rolling stock so equipped is in the electrified zones. Steam-heating may be disadvantageous, however, and the problem has been attacked by a Committee of the Union Internationale de Chemins de Fer to find a suitable means of electric heating. The standard voltages chosen are 1 500 volts (d.c.) and 1 000 volts (a.c.) for international European rolling-stock, the electric heaters being duplicated by the normal steam-heated radiators. This solution is costly and complicated, and can scarcely be regarded as convenient. The amount of energy for heating—which may exceed 25 per cent of that for haulage—is great, and must be under the control of the train staff and passengers. Further, the inter-coach couplings must be robust so as to carry currents of the order of 400 amperes. In America the most common method is to install a boiler on the locomotive, fired with oil, coal or coke, since there are no through coaches electrically heated.

(*c*) Rapid Transit.

A number of large suburban electrification schemes have been initiated or extended during the last three years. The standards of suburban working are gradually becoming defined. Modern rolling-stock is of steel construction, weighing 70 000–90 000 lb. per vehicle, and is provided with pneumatic doors for city or underground working, although several extensive suburban lines employ converted steam rolling-stock and (in Britain) retain the separate compartments with which the travelling public is familiar. Motors for normal-gauge stock are rated up to about 300 h.p., with a specific weight of 28–30 lb. per h.p. Some progress has been made in lightening motors by the use of steel frames, square field-conductor sections, forced cooling and high speeds. The schedule speeds obtainable average 18–24 miles per hour, including stops, and rates of acceleration of 1·3 to 1·5 m.p.h. per sec. are common, with correspondingly high rates of braking up to 2 m.p.h. per sec. There has been but little headway in regenerative braking, although the Ernesto Breda concern of Milan has equipped a number of tramcars with a system involving a special " dynamotor " voltage-splitting device, allowing of recuperation almost to standstill, and it appears to be operating successfully.

The mild controversy between the open (vestibule) coach and the separate-compartment coach shows no sign of nearing a solution. The open car has the theoretical advantage of reducing the duration of station stops, on account of the alleged fact that, with fewer and wider doors, passengers do not delay traffic by looking for empty compartments. The claim is by no means proved, but the chief objection to the open car is that it reduces the seating capacity. There is, however, greater space for standing passengers, which may be advantageous on lines operating with very short headway, since automatic opening of doors is more easily applied. On underground lines, also, there is rarely room for the swing-door that has been accidentally left open. Nevertheless, in this country the majority of suburban lines converted from steam working retain the compartment stock.

(*d*) Tramways and Trolley Omnibuses.

The advances in street-railway working are again principally concerned with drives. The Cardan shaft mechanism, familiar in the automobile, has been successfully applied in various forms to tramway traction both in America and in Europe. The motors are entirely springborne, and considerable benefit in the reduction of track wear has been observed in consequence. The drive, which may be collective or individual with bevel, differential or worm gears, allows of the use of high-speed motors; this is naturally advantageous in the reduction of weight. There is also a tendency to use low-voltage motors, which have better commutation at high speeds. Roller bearings have been introduced for the main driving-axles, with some gain in energy consumption on account of smaller tractive resistance and improved coasting. Attempts have been made to provide greater comfort and an improved appearance in tramway rolling-stock, with a view to the attraction of passengers in the face of omnibus competition. Operating economies have been realized both in America and on the Continent by the introduction of " one-man " cars, in which the driver operates door mechanisms and takes fares and the " conductor " is superseded. On account of the stage fare-system common in Great Britain, the scheme is here rather more difficult to apply. Regarding systems of braking, the use of pneumatic and electromagnetic brakes appears to be more common for service stops.

Certain tramway systems have been replaced by trolley-omnibus services. The introduction of these vehicles is particularly advantageous when the electrical equipment (contact lines, substations and generating stations) is already available with but slight modification. In those cities where comparative figures are obtainable, the economic advantage of trolley over petrol omnibuses has been fully demonstrated.

(*e*) Substation Equipment.

The last few years have been noteworthy for the increasing use of automatic or semi-automatic substations, and for the development for traction of the mercury-arc rectifier. The new suburban electrification in Berlin, for example, will be supplied exclusively from rectifier substations, while an example of their use in main-line service is provided by the Midi Railway of France. Several tramway systems are employing rectifier substations, among them being the Leningrad Tramways.

(2) STATISTICAL.

It is intended here to give a general outline of the developments in railway electrification which have taken place since the last review was published. It is neither possible nor desirable to give exhaustive data; and the purpose of the notes below is to draw the attention of the general reader to the fact that railway electrification is making considerable headway in certain countries, even if the developments in Great Britain seem tardy by comparison.

Great Britain.

There has been a world-wide tendency within the last decade to grapple with the pressing problem of traffic in large cities by a unification of control of transport facilities under a single authority. In New York, Chicago, Paris and Berlin, for example, a private management is responsible for the co-ordination of transport (usually confined to " rapid transit " services) whether privately or publicly owned. The necessity for similar procedure is being recognized in London, where the proposal to merge the London County Council Tramways with the Underground group (which controls certain of the local passenger railway-lines and most of the omnibuses and tramway systems not owned by local authorities) has roused great interest and some controversy. The existence of all three methods of transport has been proved essential, but the great differences in capital cost act contrary to the best economic principles if resources are not pooled and facilities developed for co-ordination rather than for competition.

The Underground group in London has, within the period of this review, confined much of its important construction work to the architectural. In this connection it is sufficient to mention the new stations at Piccadilly Circus and Charing Cross. The former was completed at the end of 1928, and the latter at the beginning of 1929. These stations are capable of dealing with 25 million and 50 million passengers per annum respectively. Each has a large circulating area with escalators, automatic ticket-issuing and change-giving machines, and coloured route-signs where necessary to guide the interchanging passenger. The new head office of the group in Broadway, Westminster, is remarkable for its modern style, great size and height, and by virtue of its unusual planning.

The power house at Lots Road, Chelsea, one of the nine largest stations in the country, had an output of over 300 million kWh during 1928. The maximum load on the station was 76 000 kW, and the annual hourly load factor 46·5 per cent. The increasing traffic on the railways has necessitated a reduction of the headway of trains, a re-modelling of station platforms, and the use of more powerful rolling-stock. The effect of this on the energy consumption has required the adoption of a scheme of improvements upon which work is now progressing. Much of the original plant which has been in service for 24 years is to be replaced. The number of boilers will be halved, but the new installation will be capable of developing over 1 000 000 lb. of steam per hour at an increased pressure and superheat. When completed, the station will comprise nine 18 750-kW machines generating at 11 000 volts and 50 cycles. The present frequency is 33⅓ cycles.

At the time of the railway grouping in 1922, the South-Western section of the Southern Railway was operating electrically 49 miles of route on the 600-volt third-railway system, while the Brighton section had 24 route-miles operating at 6 600 volts and 25 cycles, with a single-phase overhead contact-line equipment. The conversion of the latter section to direct-current third rail was completed in September 1929, and the new lines on the South-Eastern section bring the total electrified zone up to 256 route-miles or 875 track-miles, the expenditure having been £11 500 000. Eventually a service aggregating 7¾ million train-miles per annum will be provided in the electrified zone. Energy is purchased for the South-Eastern and Central sections, but the company's own station at Wimbledon is used to supply the South-Western lines. At the annual meeting of the company in March 1928, it was stated that in the electrified area the number of passengers had increased by no less than 6 millions above the figure for 1927, and the receipts had increased by £213 000. Outside that area the revenue was less by £200 000.

The directors of the Southern Railway sanctioned an expenditure of about £60 000 on further extensions to their suburban system in June 1929. This will make the Southern electrified zone easily the largest in the world, and it may astonish the British reader that this great scheme has been brought into existence so quietly and unobtrusively, while foreign efforts rarely fail to obtain their measure of publicity and praise. The new electrified zones are those between Hounslow and Windsor, Dartford and Gravesend, and Wimbledon and West Croydon, totalling 50 track-miles. The new lines involve the reconstruction of a number of stations and the provision of three new substations. A 20-minute or 30-minute service will be provided, according to the traffic. In October 1929, the Southern Railway directorate announced the electrification of the main lines to Brighton and Worthing, and the work will be completed in a few years. This will form the first main-line conversion in Great Britain (although the traffic is almost of a suburban character), and the project will be watched with interest.

The greatly improved travelling facilities now afforded to the residents in South London have necessitated new signalling equipment, and to meet this demand an extensive colour-light system has been installed at the terminal stations. The new electrical signal-box at London Bridge has been described at some length in the technical Press. The box displaces 9 manual boxes, saving the services of 35 signalmen, 4 signal-lads and 5 signal-lampmen, and effects a total economy of working expenses of about £9 000 per annum, besides the saving in stores.

Automatic colour-light signalling has also been installed by the London, Midland and Scottish Railway Company between Bow and Barking on the Tilbury section of the Shoeburyness line. At present there are 26 trains per hour in each direction during "rush hours," and the signalling system will permit of this being increased to 40 trains per hour.

An unusual development has been the completion of the London Post Office Tube, which conveys postal material over a distance of 6½ miles east and west, linking up seven important offices. The gauge is 2 ft. and the tunnel diameter 9 ft. There are three substations, each equipped with two 400-kW synchronous convertors and transformers. The conductor rail is fed at 440 volts and 150 volts. The trains, which are composed of units of three cars, each with a pair of 22-h.p. motors, attain a maximum speed of about 38 m.p.h. Their operation is automatic between stations, but ingenious semi-automatic devices are installed at stations to reduce the speed and effect correct routing. A route lever signalling-system in conjunction with track-circuiting is employed.

Some activity is reported from Manchester, where for several years proposals have been made for a system of underground railways designed to facilitate interchange of passengers between important traffic centres and to relieve the roads. Profiting by the experience of London, the Manchester proposals envisage the physical connection of the underground lines with the suburban sections of the existing main-line railways at several points in the suburbs of the city. Such a scheme, which is thoroughly modern in conception, would give unrivalled local passenger transportation, with every prospect of financial success.

Work has begun on the conversion to electric traction of the railway between Manchester (London Road) and its large southern suburb, Altrincham. The railway is 9 miles long (27 miles of single track), is known as the Manchester South Junction and Altrincham Railway, and is worked by a joint committee of the London, Midland and Scottish and the London and North-Eastern Railways. The service is expected to be at intervals of 5 minutes during "rush hours." The installation is to have an overhead contact line at 1 500 volts (d.c.), the type of construction being compound catenary with suspension insulators, and the trains will be of the separate-compartment type, seating 536 passengers when full. The line will be supplied from two substations, one of which will be remote-controlled from the other. Two new stations will be built at the Altrincham end of the line. The early conversion of this line has been hastened by the impending development of the Wythenshawe estate between Northenden and Altrincham, which has been acquired by the Manchester Corporation for housing purposes.

The Ministry of Transport Railway Electrification Committee (1927) issued in 1928 a report in which the provisions made in the 1921 Report were revised. The adoption of the direct-current 1 500-volt overhead and 750-volt third-rail systems was recommended, with the option of the 3 000-volt overhead system subject to the consent of the Ministry. Loading gauges for locomotives intended for inter-running were also prescribed.

At the time of writing, a Government Commission is sitting on the question of the main-line electrification of British Railways.

FRANCE.

The Métropolitain and Nord-Sud subways in Paris, which form a close network covering the area within the old city walls, have for many years been inconvenient for residents living in the suburbs. The *octroi* system by which much of the income of townships in France is derived, requires the inspection of all public vehicles entering the city of Paris, and has hitherto proved an obstacle in the way of extensions outward on the part of the underground lines. Authority has now been given, however, for extensions to be carried out, and it is likely that connection will eventually be made with the main surface lines. This should prove of great benefit, for at present severe congestion takes place during rush hours at the main-line terminals, at which streams of suburban passengers congregate. The Chemin de Fer de l'Etat is particularly notorious in this respect, the congestion at its St. Lazare terminus being severe. The subway extensions will enable a general efflux of passengers to take place from many points, relieving the terminal stations to a marked extent.

The State Railway already operates an extensive network of electrified lines from its St. Lazare, Montparnasse and Invalides termini. The Ministry of Public Works announced, early in 1928, that the railway from St. Lazare to Versailles via St. Cloud was to be converted to electric traction, together with the Puteaux–Les Moulineaux line.

Electric street transport in Paris is being influenced by modern conditions in the same way as elsewhere. One by one the tramways are disappearing from the centre of Paris, and are being replaced by motor omnibus services. Several tramway routes were suspended in 1928, including two which came from beyond the Place de l'Etoile to the Madeleine and the Gare St. Lazare. In the Etoile a gyratory traffic system has been introduced on account of the great increase in numbers of vehicles. Unfortunately, the tramway route runs in a direction opposite to the rotation of other traffic, causing considerable confusion at rush hours.

The main-line electrification in France is directed towards the reduction of coal imports from foreign countries and the economy realized by the use of hydro-electric power. The schemes, confined principally to the Paris–Orleans (127 miles of route) and Midi Railways (980 miles), are being slowly proceeded with. Following the principle authorized in France, the railways are being electrified at 1 500 volts (d.c.) simultaneously with the development of a great industrial 3-phase network or "grid." The hydro-electric stations of the Massif Central and at Eguzon are already linked with the great coal-fired power stations in the neighbourhood of Paris, by lines along the Paris–Orleans Railway. Financial difficulties, from which all Europe is now suffering, have retarded the progress of conversion. A recent announcement, however, provides for the electrification of the Béziers–Neussargues line, 172 miles in length, which will connect with the Neussargues–Vierzon line of the Paris–Orleans Railway, all of which is to be electrified.

Three mountain lines are projected in the Pyrenees district, and it is reported that at least two of these will be equipped for electric traction.

GERMANY.

With characteristic thoroughness the German State Railway authorities are proceeding with a programme of electrification despite financial stringency. In 1918 the lines worked electrically totalled about 190 miles of route, with an energy requirement of 23 million kWh per annum. At present there is a length of nearly 1 000 route-miles electrified, with a consumption of 325 million kWh, including all main and suburban lines. The Bavarian group of lines (Munich to Regensburg, Salzburg, Kufstein and Reutte, with branches) accounts for 430 miles, the Silesian Mountain Railways (Görlitz–Breslau) for about 220 miles, and the Central German brown-coal district (Leipzig–Magdeburg) for 125 miles of route. The choice of lines for electrification was made with reference to the traffic density, line profile, the cost of energy and the importance of the route for main-line communication or suburban traffic. Energy is obtained from power stations owned by and operated for the railway, or from mixed stations in which the railway administration has part control. Although in the interests of the continuity of supply and of the load factor the mixed station (the basis on which the French railways are being converted) is preferable, yet it has hitherto been found that the railway power stations can operate more cheaply. An attempt to apply this principle to the Berlin suburban lines, however, met with such strenuous opposition that the decision to take a supply from the existing stations at Charlottenburg, Moabit and Rummelsburg followed inevitably.

The Berlin City, Ring and Suburban Railways are being electrified at 800 volts (d.c.) with despatch. The entire zone is being fed from 115 mercury-arc rectifier installations, forming the largest scheme in the world thus equipped. The route length electrified or under conversion is about 150 miles. Steel motor-coach trains are in use, to the number of nearly 600, equipped with completely automatic camshaft control-gear.

For main-line operation the single-phase system at 15 kV and $16\frac{2}{3}$ cycles has been standardized, and after many years of experimenting a short series of suitable locomotives, the majority of which embody some form of individual-axle drive, has been evolved. Control, however, has not yet arrived at a state suitable for standardization. While a considerable extension of the electrified system is as yet scarcely possible with the present financial position, it is kept in mind that the linking-up of the isolated zones is of prime importance. Probably the first important step would be the connection of the Bavarian network at Regensburg with Berlin, via the Leipzig–Magdeburg line, and the connection of the Silesian zone to this through route, via Saxony.

SWITZERLAND.

As regards world main-line railway electrification, first place is taken by Switzerland with 60 per cent of its Federal lines electrified. The opening of the Zurich–Oerlikon–Schaffhausen line (29 miles) in December 1928 completed the first stage in the Federal programme of 1 040 miles of route, including the entire main-line mileage. The electrified sections of the Swiss Federal Railways account for 77 per cent of the total traffic of the whole Swiss railways. The other important normal-gauge line is the Berne–Lötschberg–Simplon Railway from Berne to Brigue, at the northern portal of the Simplon Tunnel. In the west of Switzerland the Rhätian Railway operates an extensive network of narrow-gauge electrified lines. Practically the whole of the Swiss electrification is on the single-phase system at 15 kV and 16⅔ cycles. The completion of the first stage of the conversion was estimated to cost at least £30 400 000, but actually cost less by nearly £5 000 000, the necessary capital having been largely raised in Switzerland by means of loans on which the railways must pay £850 000 per annum. The saving effected by electrification has more than met the charges for interest and repayment of capital.

The analysis of the capital outlay is of interest. The power stations, of 195 000 kW installed capacity, accounted for 21·4 per cent; the 1 100 km of transmission lines, 7·9 per cent; 27 substations and locomotive repair-shops, 8·6 per cent; overhead contact lines, 17·8 per cent; non-recurring expenditure, 14·3 per cent; and locomotives and rolling-stock, 30 per cent. The energy is obtained from pairs of hydro-electric stations, a river and a storage station being worked together to ensure continuity of supply. The civil engineering and installation costs amount to 87 per cent of the cost per unit, which is progressively decreasing as the capital invested becomes more usefully employed. The mean cost in 1926 was 0·57d. per kWh for 213 million units. Ultimately a figure approaching 0·3d. is anticipated. It is noteworthy that advantages have resulted from electrification quite apart from fuel saving, for, at the present price of imported coal, the cost of motive power per locomotive-mile shows little difference.

The programme for the second stage of electrification is ready. It provides for the conversion of 260 miles of branch line on the Federal Railways. It is also reported that the line through the Simplon Tunnel from Brigue to Domodossola in Italy will be converted from 3-phase to single-phase working at 15 000 volts and 16⅔ cycles, by the Swiss authorities. At Brigue two systems—the single-phase and the 3-phase—meet, and international trains require the services of a steam locomotive for the change-over. Further, from the point of view of power-station economy, the railway administration desire to dispense with 3-phase equipment. The Domodossola–Milan route will remain steam-operated at present.

AUSTRIA.

The Austrian State Railways Administration announced in November 1927 the decision to proceed no further with their electrification programme, and to utilize in other directions the funds set aside for this purpose out of the international loan. Much criticism was levelled at the Government on the grounds that the development of water-power resources was to be suspended. It was also felt disadvantageous that the Vienna–Salzburg line, not being yet electrified, prevented a through run under electric traction of 480 miles across Austria from the Swiss frontier. The Chambers of Commerce accordingly asked the Government to permit their estimates to be examined by unbiased experts, to which the Chancellor, Dr. Seipel, agreed. An examining commission sat on the problem and a majority and minority vote resulted, the majority favouring a continuance of the electrification projects. No decision as regards extensions has yet been taken, and further information is awaited with interest. Meanwhile, some experience has been acquired with the use of Diesel-electric locomotives on branch lines with light traffic.

At present, a total of 390 miles of route, including privately-owned lines, has been electrified, this total including the Salzkammergut line (66 miles), the Arlberg, the Innsbruck–Salzburg and Innsbruck–Brenner Railways.

In Vienna, the city railway has been converted to electric haulage from steam working. The installation costs for a normal rapid-transit system were too high for such a conversion, and the problem has been solved by the adoption of a tramway service, interchangeable with and connected to the street tramways. The city lines extend from Hutteldorf-Hacking to Heiligenstadt, via either West Bahnhof or Haupt Zollamt. The contact-line equipment is of the simple catenary type at 750 volts (d.c.). The street-tramway voltage is 550 volts, so that higher speeds are obtainable on the railway routes. Trains of five to nine cars of the 2-axle tramway type are run, each train comprising two or three driving-cars, the rest being trailers.

SCANDINAVIA.

Developments in Norway and Sweden have been confined principally to a number of suburban lines round Oslo, such as the Hoved Railway to Lillestrom. The main lines comprise the Lulea–Narvik or Riksgränsen mineral route (which crosses the country from the North Sea to the Gulf of Bothnia), and the important Stockholm–Gothenburg Railway. Both of these are worked on the single-phase system at 15 kV. A total of some 800 miles of route has been electrified in the two countries.

ITALY.

Further electrification of the Italian Railways has been carried out during the past two years, and the total now amounts to rather more than 1 000 miles. During the last financial year, nearly 100 million lire were spent on electrification.

The electrified lines in Italy can be roughly divided into three zones. In the north there is an extensive network of 3-phase lines at 3 700 volts and 15 cycles. The main routes are from Modane (Mt. Cenis) to Pisa and Leghorn (340 miles), and from Bolzano to the Austrian frontier at Brenner, a heavily-graded line about 56 miles in length. In the central zone the Rome–Tivoli–Sulmona Railway has been electrified at 10 000 volts, 3-phase, 45 cycles, this being the mean industrial frequency in the neighbourhood. In the south a trial has been made on the 62-mile Benevento–Foggia route with direct current at 3 000 volts, and there is a short suburban line out of Naples using the third rail. The Bologna–Florence line operates at 650 volts (d.c.). In addition there are a number of privately owned electric railways, a noteworthy example being the Turin–Ceres Railway which is operated at 4 000 volts (d.c.). The State Railway has nearly 700 electric locomotives, the majority being 2-speed or 3-speed 3-phase machines with induction motors. These have remarkably good maintenance records, in spite of the preponderance of side-rod drives. The 3-phase traction system demands the use of two overhead contact lines per track; no difficulty has, however, been experienced, although the arrangement at crossings and junctions is particularly complex.

SPAIN.

The Spanish Northern Railway has in operation, or nearly completed, the sections Barcelona–Manresa (40 miles), Moncada–San Juan de la Abadesas (67 miles), and Irun–Alasasua (64 miles), all double track at 1 500 volts (d.c.).

The Diesel-electric rail-car has made its appearance in Spain on the Pamplona–San Sebastian Railway where a number of such vehicles have been installed. The line is 57 miles in length, and runs tortuously through a part of the Pyrenees. It has a 1-metre gauge with sharp curves.

As in many other European capitals, the suburban passenger traffic in Madrid has increased greatly since 1918. The population is about 800 000. Of the projected underground railway, a number of routes are now operating. The lines are of the sub-surface cut-and-cover type, the deepest parts being 20 yards below ground-level. Some of the grades are extremely steep. Overhead contact-wires are used to supply the trains at 600 volts (d.c.), a simple wire suspension like that used on tramways being employed.

The Government, after two years of deliberation, announced a new programme of railway electrification early in 1928. All the main lines out of Madrid encounter mountainous country, making electrical operation particularly favourable, especially as much available water-power can be developed. The lines intended for electrification comprise a route length of 500 miles on the Northern Railway, centring on Barcelona, Bilbao and Madrid, 380 miles on the Southern Railway, between Barcelona, Tarragona, etc., and 385 miles on the Andalusian Railway Co.'s lines, embracing Bobadilla and Granada. This great scheme will require the strengthening of tracks and bridges for heavier and faster trains. The estimated cost of the conversion, which is to be carried out at 1 500 volts (d.c.), is 300 million pesetas.

OTHER EUROPEAN COUNTRIES.

No reports from Russia are yet thoroughly reliable, but the Union of Socialist Soviet Republics is said to be seriously contemplating railway electrification. Diesel-electric locomotives have been purchased from Germany, with a view to trials on the long Asiatic lines where water may be very scarce.

The only electric railway of importance in Holland is that between Rotterdam and Amsterdam, which is operated at 1 500 volts (d.c.).

The railways administration of Czecho-Slovakia in 1924 legalized the use of the 50-cycle industrial network for main-line railway electrification; direct current at 1 500/3 000 volts was therefore chosen as a standard system and a start made with the suburban lines round Prague. Some of these were inaugurated in February 1928. The lines centre on the Wilson terminal station. Locomotives for both passenger- and goods-train haulage are employed. Further developments will, as usual in Central Europe, depend on the economic situation, but probably the route Prague–Ceska Trebova (102 miles) will be undertaken next, since this line carries heavy traffic aggregating 95 million gross ton-miles per annum.

Hungary has little water power, and energy production rests almost exclusively on the limited fuel deposits, which, at the present rate of consumption, can scarcely last more than 50 years. While railway electrification is expected to help this situation, it is felt that a system applicable most directly to the industrial network is essential in order to obtain the highest load factor and economy. Consequently the high-voltage, normal-frequency, single-phase system devised by K. von Kandó, of the Ganz Co., Budapest, has received attention. This involves distributing the phases of the industrial 3-phase supply along the route in order to obtain balance of the traction load as far as possible, and using synchronous phase-convertors on the locomotives with 3-phase traction motors of the induction type. A locomotive of this type was built in 1924 and underwent trials near Budapest. The economic situation in Hungary, however, is so bad that the expenditure necessary for electrification cannot yet be contemplated.

UNITED STATES OF AMERICA.

After a short period of comparative quiescence, railway electrification in the United States has recently shown a revival. Road competition is probably more severe in America than elsewhere, even the trans-continental trunk routes having been duplicated by luxuriously-appointed fast motor-coach services.

Several suburban rapid-transit schemes have recently been put into operation or their future electrification announced. The Illinois Central terminal electrification was inaugurated in 1926 in connection with the Lake Front Improvement plans, and is in successful operation. The Baltimore and Ohio Railway electrified its Staten Island (New York) suburban lines in 1924–1926 under legislation providing for smoke abatement, and to conform to possible future operation as a part of the New York City Rapid Transit system. It is noteworthy that the co-ordination of all forms of public transport in large cities is receiving great attention in America. The Long Island Railway, a subsidiary of the Pennsylvania Railway, is the largest suburban electrified system in America, and transports over 100 million passengers per annum. In New York City proper, several extensions have been made to the subway and elevated railways. There are about 210 track-miles traversing the city. Some criticism has been levelled at the distribution of these lines; it is pointed out that 86 per cent of the city's population is concentrated in 97 square miles of area in which a good rapid-transit service is available, the remaining 14 per cent being spread over 202 square miles where the facilities are poor. This, it is alleged, indicates the manner in which a population will follow rapid-transit facilities.

Transit Companies into a homogeneous system, and power will be purchased from the Edison Co. The plans show a scheme of co-ordination on a scale hitherto unequalled.

A route length of 9 miles of subway now accommodates

SUMMARY OF ELECTRIFIED LINES, 1929.

* The figures in brackets indicate the frequency.

A recently announced scheme, involving the ultimate expenditure of 1 000 million dollars, provides for the construction of new and interconnecting subway lines in New York City. Eventually all the city-owned subways will be consolidated with the lines of the Interborough Rapid Transit and Brooklyn Municipal

a rapid-transit system at Rochester, the lines having been laid in what was formerly the Erie Canal.

A new subway/elevated system has been built at Philadelphia. The line runs out from Broad Street, and embodies all modern features of this type of service, including automatic couplers and doors, colour-light signalling, track-circuit control, train-stops, etc. Six-car trains, accommodating a maximum of about 1 200 passengers, are run during busy periods with a 2-minute headway.

Announcements are made of the electrification in the immediate future of the New York City suburban lines of the Delaware, Lackawanna and Western Railway to the extent of about 65 miles of route. The system chosen is 3 000 volts (d.c.), with multiple-unit rolling-stock. The cost of conversion is estimated at 14 to 18 million dollars. The Cleveland Union terminal and its approach lines, totalling 16 miles of track, is also to be electrified. Trains will be handled by 204-ton passenger locomotives, each rated at 3 000 h.p.

Philadelphia has already a suburban electrification in the local lines of the Pennsylvania Railway which have recently been extended. The Reading Railway Co. has announced the conversion of 50 miles of route in this neighbourhood at a cost of 20 million dollars. The same system will be used, viz. single-phase at 11 000 volts and 25 cycles. It is expected that the Bethlehem–Pottsville line will next be converted, and there is a possibility that the Philadelphia–New York main route will eventually be electrified.

As regards street transport, much activity is manifested in speeding up services and modernizing rolling-stock. Mention may be made of the street-car subway under construction at Los Angeles between Hill Street and

SUMMARY OF ELECTRIFIED LINES, 1929—*continued.*

* The figures in brackets indicate the frequency.
† Being converted to 15 000 volts, single phase, 16⅔ cycles.

Glendale on the Hollywood and San Fernando Valley route. The territory served by this route has had a remarkable growth during the past three years, and at the same time traffic congestion in Los Angeles has become acute. The new line will serve the former and relieve the latter.

Articulated trams, resulting in a flexible but compact train, have made their appearance in several American cities, and in a few instances trolley omnibuses have successfully replaced street tramways.

The conditions of main-line railway electrification in America differ from those in Europe, and the reasons for electrification are correspondingly different. The motive of coal conservation is unimportant, and the use of water-power is scarcely more than incidental. More usually the difficulties of tunnel operation, mountain grades, the smoke nuisance, or increase of terminal capacity, are responsible for electrification. The Chicago, Milwaukee and St. Paul Railway, for example, has a main route over which the traffic is scanty. Electrification was undertaken to overcome the difficulties of steam traction on heavy gradients and in severe weather.

The largest main-line railway electrification, as regards traffic hauled, is the New York, New Haven and Hartford Railway, which operates its main line from New York City into New England at 11 000 volts and 25 cycles, single-phase. The details of this line are probably familiar to engineers in Britain, especially as much experimental work in locomotive design and the elimination of telegraph and telephone interference has been carried out. The Norfolk and Western and the Virginian Railway electrifications—both for heavy coal traffic in hilly districts—are also familiar, although of more recent origin.

An announcement of great importance was made in 1928 by the authorities of the Pennsylvania Railway when the decision to convert the main line from New York City to Wilmington, Delaware, and eventually to Washington, was announced. This great scheme involves 330 miles of route electrified on the single-phase system at 11 000 volts and 25 cycles, and the provision of 365 electric locomotives. The total cost is estimated at 100 million dollars, of which 40 million are for rolling-stock. The first section, from Philadelphia to Wilmington, is now complete, and the next, from Philadelphia to Trenton, N.J., is under construction. This scheme is the most extensive and costly yet undertaken in route length, traffic volume and density, and equipment. In connection with the project a new passenger station is being built in West Philadelphia, and the existing suburban services will be diverted into a new underground terminal station adjoining the present Broad Street Station. The reasons for electrification are, briefly, for economy and the relief of congestion, for increasing revenue, and for handling through-passenger service into the underground terminal stations at New York and Philadelphia. Connection will be made with the New York, New Haven and Hartford Railway at Hell Gate Bridge, so that through electric trains will be made possible from New England via New York into the Southern Atlantic Coast States. This will be especially advantageous for freight traffic.

The developments on the Cascade Tunnel division of the Great Northern Railway were mentioned in the last review. The new zone extends from Everet on Puget Sound to Wenatchee through a new tunnel which is being constructed through the Cascade Range. The line is of interest more particularly on account of the change of system made; it was formerly the sole example of 3-phase electrification in America, but has now been changed to single-phase at 11 000 volts and 25 cycles.

The 22 000-volt, 25-cycle electrification on the Detroit, Toledo and Ironton Railway is being extended. The locomotives used are of the motor-generator type, and are of unique design in that the entire weight is carried on the motor-axle bearings, there being no side frames or axle-boxes as usually understood. There is a possibility that this 25-mile zone will be extended by 400 miles to the Ohio River.

Further tentative announcements relate to the proposed extension of the New York Central Railway (which already operates a direct-current system near New York City) to Buffalo, at a cost of 150 million dollars. If this project materializes, it is probable that the single-phase system will be used.

CENTRAL AND SOUTH AMERICA.

Two new lines are due to start electric services in Central America by the end of 1930. The normal-gauge railway just built between San Felipe and Quezaltenango, in Guatemala, is being equipped for direct-current working at 1 500 volts. Motor-coach trains will be run on this 28-mile route, which has grades as steep as 1 in 11. The narrow-gauge line in Costa Rica between the capital, San José, and the port of Puntarenas, is being electrified at 15 000 volts and 20 cycles, and its whole length of 80 miles will be supplied from a single feeding-point. Both these railways will obtain energy from hydro-electric sources.

The section of railway from Los Andes, Chile, to Mendoza, Argentina, constitutes the Transandine Railway which forms the central link between the Pacific and Atlantic coasts. It has a 1-metre gauge and is laid for combined rack and adhesion service. Although the actual volume of traffic did not itself justify electrification, the exceptionally severe winter weather and the difficult grading made the conversion advisable. At present the Rio Blanco–Los Cuevas section has been electrified at 3 000 volts (d.c.). The Chilean State Railways are already electrified on the same system between Valparaiso, Santiago and Los Andes.

Extensions have been made to the Paulista Railway, Brazil, on account of the excellent results of the initial stage. Further work has also been done in the Buenos Ayres suburban zone.

During the last two years the Campos dao Jordac Railway has been electrified at 1 500 volts (d.c.) with overhead contact-line. The motor coaches have direct control, i.e. the switching operations are made in a drum controller. In Venezuela the La Guaira–Caracas Railway has been electrically equipped on the same system. A number of Diesel-electric rail coaches have been supplied to Uruguay from this country.

CANADA.

It is reported that developments may be expected in Montreal, where the problem of new terminal facilities has been investigated. As with a number of cities in America and Europe, the elimination of the locomotive smoke nuisance and the increase in value of land and buildings due to electrification indicate the use of an underground terminal station with its immediate zone electrified.

The electrification of the line belonging to the Montreal Harbour Board has been completed, and the service along 11 miles of waterfront is now maintained by electric locomotives. The system is 2 400 volts (d.c.) and the 100-ton locomotives are each equipped with four 400-h.p. motors. The service is of a heavy shunting type, with train weights up to 5 000 tons or more.

The Canadian National Railways have a number of oil-electric railway vehicles in use, including the 290-ton, 2 660-h.p. double-unit locomotive now operating between Brockville and Belleville, Ontario.

INDIA.

The first stage in the electrification of the suburban services of the Bombay, Baroda and Central India Railway was opened at Bombay by the Governor on the 5th January, 1928. The lines extend out northward from Bombay through Salsette Island into which the suburbs are rapidly spreading.

The important scheme of the Great Indian Peninsula Railway in the neighbourhood of Bombay, including the main lines to Igatpuri and Poona, mentioned in the last review, has now been completed. The 1 500-volt d.c. overhead system is used. Several 2 600-h.p. freight and 2 160-h.p. passenger locomotives for this railway have recently been supplied from this country. The form of drive shows a departure from the nose-suspension type more commonly supplied. The goods engines are of double 6-wheeled coupled-bogie pattern with 2 motors per bogie geared to a jack shaft. The passenger locomotives have a flexible individual-axle drive with double-reduction gear and a form of the Oldham universal flexible floating coupling between the centrally-placed gear wheel and the driving axle.

Proposals, on a large scale, for the construction of a tube railway in Calcutta have been worked out. The scheme would cost £4 000 000 and would be put forward in conjunction with a project for the electrification of the suburban lines of the East Indian and Eastern Bengal Railway. A suburban and city electrification scheme has also been devised for Madras.

AUSTRALIA AND NEW ZEALAND.

In Australia the Sydney suburban and city railways are being proceeded with. The plans involve the interconnection of a new subway network with the existing suburban tracks of the surface railways—a scheme which is completely modern in its conception, since it provides a definite forward step in the co-ordination of the city's transportation facilities. Several sections of the scheme are in operation.

In New Zealand, the first electric train on the 7-mile Christchurch–Lyttelton line of the Government Railways ran on the 14th February, 1929. The 1 500-volt d.c. system is used. In recent years the limitations of the 1⅝-mile single-line tunnel between Lyttelton and Heathcote have proved increasingly severe, and the decision to electrify followed inevitably. The single substation is fed from the New Zealand "grid" network, and is equipped with single-commutator rotary convertors.

The first electric railway in New Zealand was the Otira Tunnel section (Arthur's Pass), completed in 1924.

SOUTH AFRICA.

The rapid expansion of the suburban traffic in the vicinity of Cape Town during the second decade of this century led, in 1917, to the appointment of consultants to report on the matter, and also on several other sections of the South African Railways. The period of depression retarded any realization of the consultants' findings, but provision was made during 1924–5 for some 26 miles of the 3 ft. 6 in. gauge suburban lines near Cape Town to be converted for electric traction at 1 500 volts (d.c.). A power house at Paarden Island, Salt River, supplies six substations serving the Cape Town–Simonstown and Cape Town–Sea Point routes. The effects of road traffic have been severely felt.

The Glencoe–Pietermaritzburg line, in Natal, is now completed and has been functioning efficiently for two years. The financial results are disappointing, on account of the increase in traffic not coming up to expectation, and of the greatly increased costs for energy, consequent upon the transfer of the Colenso power station to the Electricity Supply Commission. An increased expenditure of approximately £90 000 per annum has been involved, and this has rendered the immediate extension of the electrified zone to Durban financially uneconomical.

MOROCCO.

Electric operation has been in use since 1927 on the Casablanca–Kourigha and Casablanca–Rabat Salé routes, a total of 160 miles. The lines are heavily graded, making the equipment of some of the locomotives with regenerative apparatus an economic necessity. The system used is 3 000 volts (d.c.) and several motor-coach trains are working with this voltage on suburban services. Energy is obtained from both hydraulic and thermal stations.

JAVA.

The island of Java, in the Dutch East Indies, is extremely fertile and supports a large population. With a view to more efficient transport and the utilization of existing water-power, the railway authorities embarked on a scheme of electrification in 1921. Up to date a route length of 56 miles is worked at 1 500 volts (d.c.), with overhead contact line, from a hydraulic station at Oebroeg. The initial part from Meester Cornelis, Batavia (the capital) to Pasar Senen and Tandjong Priok was opened in 1924–5. An extension from Manggarai to Buitenzorg was put in service in 1928, together with some local lines at Batavia. Locomotives are used, and both synchronous convertors and mercury-arc rectifiers are being tried in the substations.

JAPAN.

The first electrified railway in Japan was a short suburban section at Tokyo, which has since been extended to a route length of over 60 miles. Trains of

4 to 8 coaches are run with a headway of 2 to 12 minutes. The electrically-operated routes comprise a circular line, a line running west to Yokohama and Sakuragicho, and a route running diametrically across the circle from north to south, then turning west to Kokobunji.

After the War, attention was drawn to main-line conversion, in connection with the use of available water-power and the elimination of smoke from trains in Tokyo. A scheme for the electrification of about 400 route-miles was prepared and work began in 1922. By 1924 the Tokyo–Odwara main 4-track line had been electrified, together with a short branch. A total of about 70 electric locomotives are in service on this line. An overhead contact arrangement at 1 500 volts (d.c.) is used for the main lines and 1 200 volts for the suburban routes, on which motor-coach trains work. Some of the recent locomotives have been constructed entirely in Japan. During the last two years a total of 18·6 miles of Government route have been added on the 1 200/1 500 volt (d.c.) system, while 185·5 miles of privately-owned lines have been equipped, all on the d.c. system at 600 or 1 500 volts. A route length of 326 miles will be added to the Government lines by 1934, and a further 60 miles of private route is due for completion in the immediate future.

A short underground railway has been in operation in Tokyo for some years, and it will eventually be extended. At present, however, the heavy cost of underground construction prevents any further work.

The rack railway over the Usui Pass has been electrified at 650 volts. The line has grades up to 1 in 15 and long tunnels, and great difficulties were encountered when the line was steam-operated before the conversion.

TEES-SIDE SUB-CENTRE: CHAIRMAN'S ADDRESS

By J. M. Gibson, Associate Member.

"THE PROGRESS OF ENGINEERING AS APPLIED TO AGRICULTURE."

(*Address delivered at* Middlesbrough, *16th October*, 1929.)

Under the powers given to the Electricity Commissioners by the recent Electricity (Supply) Acts it is proposed to create in this country a great distribution system fed by highly efficient generating stations. The main object of this proposal is to produce electricity as economically as possible and make it available for distribution throughout the country, and thus to extend its use beyond the limited areas in which it is now available.

The needs of our cities and urban areas have already been provided for to a very great extent, but it may reasonably be said that the rural portion of the country is virgin soil to the great majority of supply undertakings.

The provision of the main trunk routes by the Commissioners has relieved the distributors of the necessity of spending vast amounts of capital in this direction, thus making it possible for them to spread out their distribution lines into the less thickly populated areas.

Before embarking on a scheme of rural distribution it is necessary to consider what channels are open for the utilization of electricity in rural areas. There are four main channels: (1) Lighting and heating, (2) local industries, (3) irrigation (in some parts of the country only), and (4) agriculture.

There is no doubt that an efficient and reliable source of artificial lighting will be of great value in rural areas, and it is reasonable to assume that there will be a certain demand for heating, particularly in areas remote from the coalfields.

Local industries have, in a great many instances, long felt the need of a cheap motive power which would help them to return to a state of prosperity.

Irrigation schemes such as are in operation in some areas could undoubtedly be improved by the use of electricity.

The application of electricity to agriculture, however, is a subject of many possibilities and a great many difficulties, and in the hope that a better understanding of these difficulties will assist in the development of rural electrification schemes it is my intention to make a brief survey of "The progress of engineering as applied to agriculture."

We are told by archæologists that engineering in its simplest forms was first applied for purposes of war and agriculture—for war, for the purposes of making arms and armour, and in agriculture for the manufacture of cultivating tools such as sickles and ploughshares. It has been proved that such implements were in use as far back as the days of the ancient Egyptians, and it is an interesting fact that those implements in almost their original form are still in use in this country.

Little can be said about the need for the application of engineering to agriculture in any form during the period prior to the sixteenth century. In the early days man tilled the soil only to provide for his own needs, and in the latter part of that early period the land was in the hands of warlike barons and similar men, who made the local inhabitants into serfs and soldiers. Under such conditions progress, as we understand it, could not very well be expected.

Such machinery as windmills, water wheels and treadmills are known to have been utilized at an early date, but it was not until about the middle of the eighteenth century that the inventive mind began to produce machinery for general use in agriculture.

During the sixteenth and seventeenth centuries comparatively rapid strides were made with the invention and improvement of implements for the main agricultural operations.

Following James Watt's discovery of a method of utilizing steam as a motive power, it is recorded that he took out a patent for steam ploughing in the year 1770, but little progress was made in this direction until nearly a hundred years afterwards, and even after that date progress was very slow.

Machines for sowing seed appear to have been introduced in the seventeenth century. Joseph Locatelli of Corinthia invented such a machine in 1662. Some of his machines were imported into this country, but in 1783 Cooke, a Lancashire clergyman, patented a drill, the principle of which was to be the foundation of all drills now in use. Similarly, threshing machines were devised by Menzies in 1732, being improved in 1758 by Leckie and in 1786 by Meikle, whose ideas are embodied in most modern machines.

Harvesting machines were not developed until 1808, improvements being brought forward in 1826, 1849, 1851, 1878 and 1879, and during the last-mentioned two years the forerunner of the string binder now in use was produced. It is interesting to note that a clergyman was again amongst the inventors of this machine. Mowing machines were introduced in 1852 and another type was produced in 1854. This latter, with the addition of certain improvements, became, in 1860, a machine representative of a present-day production.

Numerous other machines of less importance were introduced during the first half of the seventeenth century, but all these required the use of horses to provide the motive power, with perhaps the exception of the large American machines which were later hauled by steam engines, and the larger portable threshing machines in use in this country, which were, and still are, hauled and worked by steam engines.

The year 1903 brought a new form of prime mover into the agricultural world, in the form of the Ivel motor tractor. This type of machine, although used to a small extent in 1910 for ploughing, did not come seriously into the agricultural field until the Food Production Campaign of 1917–18, when horses and men were difficult to obtain for farm work. These machines proved to be such an asset in agriculture at that time that, although only a few existed in 1908 and 1913, yet in 1925 there were 14 565 in use for field operations and 2 116 in use for stationary work.

The greater proportion of mechanically provided power utilized in agriculture during the last 20 years or so has been obtained from steam, oil or petrol engines, as revealed by the following returns.

	1908	1913	1925
Steam engines	8 690	7 719	3 731
Oil or petrol	6 911	16 284	56 744
Gas, wind, water, electric and other machines . .	1 730	5 240	5 254

It will be noticed that the use of oil and petrol engines increased very rapidly. Apart from the machinery which has been directly applied to farm work it should here be mentioned that that great branch of our engineering industry, the railways, has played a very important part in the advancement of agriculture.

Having briefly considered the history of engineering as applied to agriculture, let us now consider the possible causes of its slow growth as compared with engineering in other industries. This I propose to do under three headings, viz. (1) Psychological, (2) social, and (3) commercial.

(1) *Psychological.*—Agriculture is known to be one of the oldest industries, and the earliest date at which attempts were made to obtain a subsistence by the tilling of the soil may perhaps be as far back as Biblical days. In any case it has been proved, so far as this country is concerned, that the ancient Britons did a certain amount of farming. It is doubtful, however, whether any serious attempt was made to extract from the soil a reasonable yield of the riches it contains, until the many foreign invasions with which this country was afflicted came to an end.

It is probable that at this time those who laboured on the soil were driven to it by task-masters or were forced to cultivate the soil in out-of-the-way places, where they would not be molested, in order to obtain food. From this state of things our agricultural industry appears to have slowly but surely grown, and if such were the circumstances under which the farmer began to exist it is not surprising to find that in the main he is of a reserved and retiring disposition and not too prepared to accept anything new without definite proof of its worth.

In the process of time the ever-present fear that his next-door neighbour might raid him for the sin of holding opposite political opinions, or that the nearest baron might find some means of taking his land and impressing the services of himself and his family, has undoubtedly died down, but it seems to have left the seed of mistrust in the hearts of the farmer and the rural dweller.

The conditions under which the early farmer lived in isolated areas, before roads were made, tended to make him a confirmed individualist, and although the introduction of transport facilities, in the form of roads, and education did bring about social changes he remains an individualist.

(2) *Social.*—From this point we may consider the social changes which have taken place in rural areas during the last decade.

It has previously been noted that clergymen were responsible in some cases for the development of new ideas in machinery. Here education begins to enter forcefully into the agricultural field. Later the Church schools put forth a helping hand and then in 1870 the "school board" national education system was instituted, this being again revised by the Act of 1902. Although this probably resulted in a large number of the more healthy-minded young men leaving the land to seek their fortunes in other spheres and industries, yet education has been an enormous influence for the good of the farm and rural dweller.

The introduction of transport facilities by means of roads and railways has further expanded their social outlook, to the extent of producing almost a different type of people. Whilst the evolution of mind has slowly progressed, so has the adoption of improved methods of cultivation advanced, so that whereas 50 years ago a new machine was looked upon by the small farmer and farm labourer as a nine days' wonder, he now recognizes the ordinary agricultural machine as a necessity and a friend.

The more recent improvements in educational methods, together with the intensive developments of transport services, which enable country children and youths to attend better schools, are exerting a greater influence upon the minds and lives of the rural dweller.

As the result of these changes it will be found that the electrical engineer is entering the field with the way infinitely better paved than it was for the mechanical engineer, although many of the old prejudices and doubts still exist.

(3) *Commercial.*—Although the personal element has had, and will continue to have, a great influence on the development of engineering in the agricultural world, yet it is the financial outlook which really governs the industry.

Farming has almost solely been a one-man business and since the days when he traded by barter the farmer has been noted as a bargainer who desires worth for worth. He has a deeply-seated dislike for trading on borrowed money, and would rather work his hands bare to the bone on a piece of land he has sufficient capital to stock, than work a larger farm on capital on which he has to pay interest and which has to be redeemed.

The basis of the farmer's financial law is, as in all other industries, that he shall so balance the cost of producing his final saleable article with the capital he has invested, mainly represented by stock, that at the end of each year he can have a reasonable return on his capital. The means by which he obtains this balance must of necessity depend on the class of farm he works, i.e. whether it is a dairy farm, a sheep farm or a mixed farm. Each class of farm presents its own peculiar problems.

Closely coupled with the question of stocking a farm is the question of manning it efficiently and providing the necessary amount of power, either in the form of horses or mechanical contrivances, so that he will not have to pay out more revenue than is necessary on hired labour, nor have more capital invested in machines which cannot be profitably employed, than he can afford. The words "profitably employed" are very significant when applied to agricultural machinery. Although there are a great number of operations which can be carried out on a farm by mechanical means, yet there are practically none which can be designated as continuous processes. The greater proportion of these operations occupy only a few minutes per day, or possibly a few days per annum. On the other hand, man-power is required constantly in all operations on the farm, and the problem of how much such revenue-absorbing help can be supplanted by capital-absorbing machines is one which needs very careful thought. The same consideration has also to be given to the use of mechanical power in place of horses. It is perfectly true that machines can be made use of, but the farmer has to decide whether they can be used more profitably than men and horses in each particular circumstance.

Some idea of the acuteness of this problem may be gathered from the following figures relating to the value of stock and machinery:—

Sheep	Stock to buy: £2 Fat for sale: £3 10s.
Cattle	Stock to buy: £14 Fat for sale: £20–£22
Oil or gas engines	£50
Harvesting machines	£56
Mowing machines	£25
Drills (seed and manure)	£24–£30

Thus the farmer can buy 25 stock sheep or 3 stock cattle for the price he would have to pay for an engine. The sheep and cattle will live and fatten on the products of the soil, and eventually sell at such a price as to return him his capital plus a profit, whereas the value of the engine decreases with time and use. The purchase o the engine must therefore depend on whether or not its use will save for him, in other expenditure, more than that stock would return to him.

Having considered all the circumstances the farmer becomes faced with the fact that he can only afford to expend a very small proportion of his capital on machinery; hence it is that only on the larger farms are the more expensive machines to be seen at work.

Mr. Borlase Matthews in his paper * read before the Institution in 1922 mentioned that, in England and Wales, out of a total of 418 000 farms and small-holdings only 36 000 (or 9 per cent) of these were over 150 acres in area, and only 13 500 (or 3¼ per cent) over 300 acres. Mr. Matthews also mentions that for farms under 150 acres careful thought must be given to ensure that an adequate return is obtained on the capital expended. This remark should not be interpreted to mean that farms below 150 acres in area would not be worth supplying, but rather that a great deal of thought would have to be given to the question of how best to apply the capital the farmer could afford to lay out in machinery and other labour-saving devices.

The electrical engineer has at his disposal infinitely more useful and adaptable appliances than the mechanical engineer has had. Not only can he offer to his client the heavier type of power unit, and an efficient and safe method of lighting, but he can introduce an infinite number of smaller labour-saving devices of which the farmer and his wife do not appreciate the need, because they have been so accustomed to doing things by hand.

In approaching the farmer it will not be sufficient to tell him that such and such things can be done. He may believe it, but he will not appreciate to the full what it would mean to him.

As I have already mentioned, the farmer is a reserved man and a bargainer, desiring to know the worth of all things before he will commit himself to purchase them. He knows little or nothing of what electricity is capable of performing, therefore if success is to be attained in rural development the electrical engineer must be prepared to demonstrate to him those capabilities, and above all to give him all the assistance in his power to enable him to lay out his capital in the most economical manner.

To press on to him an ill-considered scheme will end in creating mistrust and tend to bring about the failure of rural electrification.

SOME MEASUREMENTS IN CORNWALL OF THE SIGNAL STRENGTH FROM 5XX.

By J. H. Reyner, B.Sc., Associate Member.

(*Paper first received* 10*th October, and in final form* 19*th November*, 1929.)

Summary.

In connection with the testing of wireless receivers, information was desired concerning the field strength obtained from 5XX in Cornwall, this district being known to be poor from the point of view of wireless reception.

An investigation of the field strength was therefore carried out with the aid of portable equipment. This particular apparatus was simpler than that usually employed but appears from the consistency of the results to be reliable.

When the experiments were conducted, a curious effect was brought to light which appeared to be a radio shadow caused by the masts of the beam station at Bodmin. This gives rise to an interesting distribution of the contours in the Truro district.

The general order of field strength appears to coincide with theory up to this point, if due allowance is made for attenuation, but there is a rapid falling-off towards the extreme west of Cornwall.

(1) Apparatus Employed.

For certain reasons in connection with receiver testing it became desirable to obtain information regarding the signal strength of Daventry 5XX in Cornwall, as the evidence obtained from reception tests appeared to indicate a more rapid attenuation than normal. A simple portable equipment was therefore constructed, and a series of measurements was made covering a wide area. A small aerial and counterpoise system was used, the masts being in three sections so that they could readily be dismantled. The signals received on this aerial system were applied to a screened receiver comprising one stage of high-frequency amplification followed by an anode-bend rectifier.

A screened local oscillator was employed in conjunction with the equipment, the method of taking the measurements being as follows. The receiver was tuned in to 5XX and the rectified current in the anode circuit of the detector valve was measured by means of a sensitive microammeter. The receiver was then switched over to a dummy aerial having the same characteristics as the actual aerial system. In this circuit was included a coupling coil from the screened local oscillator, the output from which was adjusted to produce the same rectified current as before.

Provided that suitable obvious precautions are taken, such as ensuring that the oscillator is correctly tuned to the receiver, this method gives consistent and reliable results. The amplification of the receiver employed may vary from day to day, but since it is only used for the purpose of providing a visible indication of the rectified current the actual amplification is immaterial, the point which is important being the output from the oscillator.

The oscillator was straightforward in character, consisting of a simple valve-maintained oscillating circuit to which a small pick-up coil was coupled. The inductance of this pick-up coil was kept small, only a few turns being employed, and the distance from the main tuning coil carrying the oscillating current was sufficiently great to render the capacity coupling negligible. Under such circumstances, the voltage induced in the pick-up coil is proportional to the current in the oscillating circuit and to the number of turns on the coil itself. The oscillator was so calibrated that the voltage induced in the pick-up coil was known in terms of the oscillating current, for each of the pick-up coils used.

A thermo-couple was included in the oscillating circuit, and the leads from this were taken to terminals on the case of the oscillator to which a meter could be connected externally. The H.T. voltage on the anode of the oscillating valve was made variable by means of a suitable high resistance, and by this system it was found practicable to control the oscillating current within wide limits and thereby to vary the induced voltage from 0·1 to 3 mV. This was found to be more than sufficient to cover the range of field strength encountered during the tests.

By means of this equipment, therefore, it is possible to measure, in any desired locality, the actual voltage in millivolts set up in the aerial by the radiations from 5XX. If the effective height of the aerial system is known it is possible to convert these figures into field-strength values. The best way of doing this is to measure the field strength from 5XX with the same apparatus at some point relatively close to Daventry such that the field strength is sufficiently large to be measured directly. For this purpose an absolute measurement of the signal strength from 5XX was taken at the author's laboratories at Elstree, and at the same time a reading was taken on the portable equipment. This enabled any readings obtained with the portable apparatus to be converted to millivolts per metre by direct comparison, and at the same time enabled the effective height of the aerial system to be ascertained. The dimensions of the aerial system are shown in Fig. 1.

For the absolute measurement of signal strength a large frame aerial of 4 ft. side was constructed and this was arranged to tune with a relatively small value of capacity to Daventry's wavelength. A sensitive valve voltmeter was connected across the tuned frame, and the reading on this meter was observed when the frame circuit was tuned to resonance.

The frame was then placed at right angles to the maximum position, in which case no signal was induced from 5XX, and a voltage was set up in the frame from a calibrated source. This voltage was adjusted until the deflection on the valve voltmeter was the same as before.

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

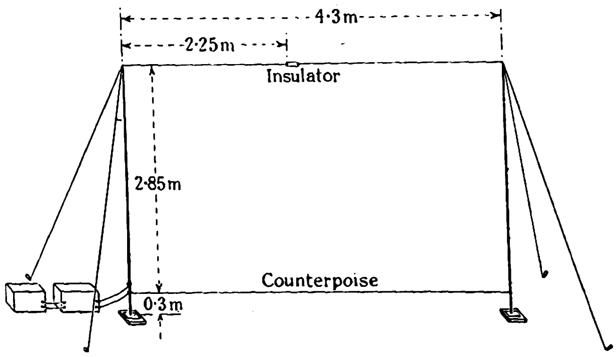

FIG. 1.—Arrangement of aerial system.

In order to check any serious error two methods were employed for inducing the necessary voltage in the frame aerial.

The first method consisted in the use of the same screened calibrated oscillator as was used with the portable aerial. Knowing the voltage induced in the various coupling coils per milliampere of oscillating current, it was a simple matter to determine the actual voltage induced in the frame. The second method consisted in introducing a 2-ohm resistance into the frame circuit. An oscillating current was passed through this resistance and the current was adjusted until the meter deflection was the same as before. The product of this current and the resistance gave the induced voltage.

Both methods gave consistent results in good agreement one with another. From the values of induced voltage so determined the field strength in millivolts per metre is easily evaluated from the well-known formulæ for frame aerial reception. As a result of these calculations, the field strength from 5XX at Elstree was found to be 12·5 millivolts per metre, a value which, as indicated in Section (3), is in good agreement with theory.

(2) RESULTS OBTAINED.

The first tests consisted of a series of readings taken at selected points in the county in order to obtain some idea of the general contour to be expected. At first, there appeared to be little unusual, beyond the fact that the signal strength was lower than had been anticipated. Moreover, it was at once apparent that the contours were not circular or even approximately so in formation, being rather in the nature of a wedge in which the high signal-strength areas extended further west inland than on the coast. It was as if the coast-line were exercising some marked absorbing effect. Apart from this, however, the contours were not unusual, being of the general character indicated in Fig. 2.

Acting on this first rough contour, a number of further readings were taken and the results obtained were compared with the theoretical expectations. The figures were not in agreement and the discrepancies were for some time very puzzling. In some cases the signal strength would be distinctly lower than was anticipated, while in other cases it would be higher. Another curious effect was that in the Perranporth district the signal

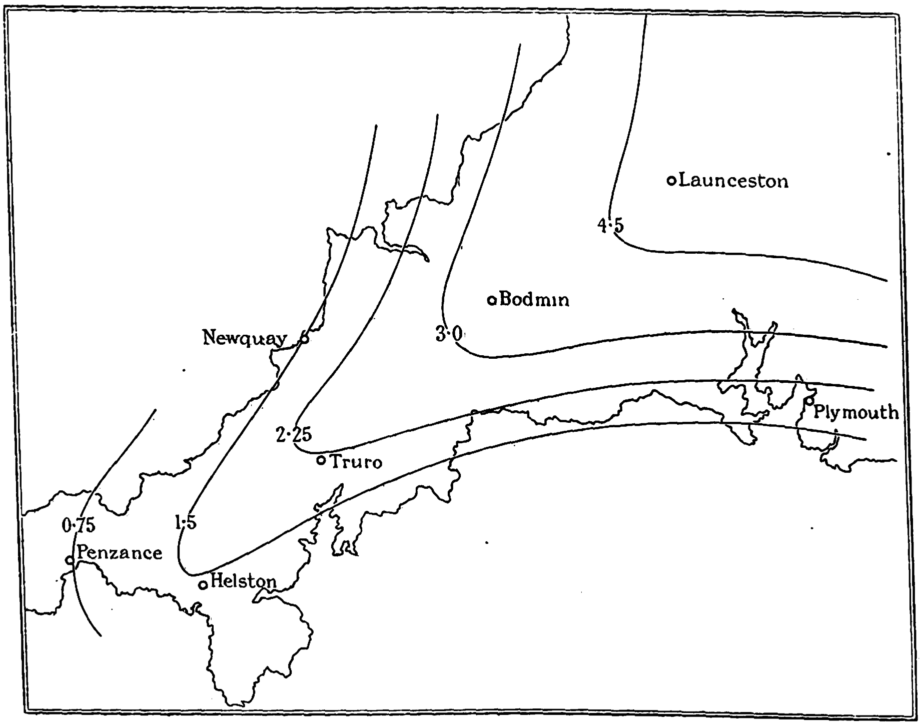

FIG. 2.—Apparent contours after first tests.

strength on the coast-line is approximately half that on the hilltop, only two miles inland. This effect was confirmed by the local residents who had noticed a marked difference in actual reception in the two localities.

In the course of the investigations, however, the breasting of a hilltop one day suddenly brought into view the masts of the Bodmin beam station and this immediately suggested the possibility of a radio shadow. The results so far obtained were re-examined in the light of this possibility and appeared to give some confirmation of the view. Further investigations were therefore put in train in order to confirm or disprove the theory.

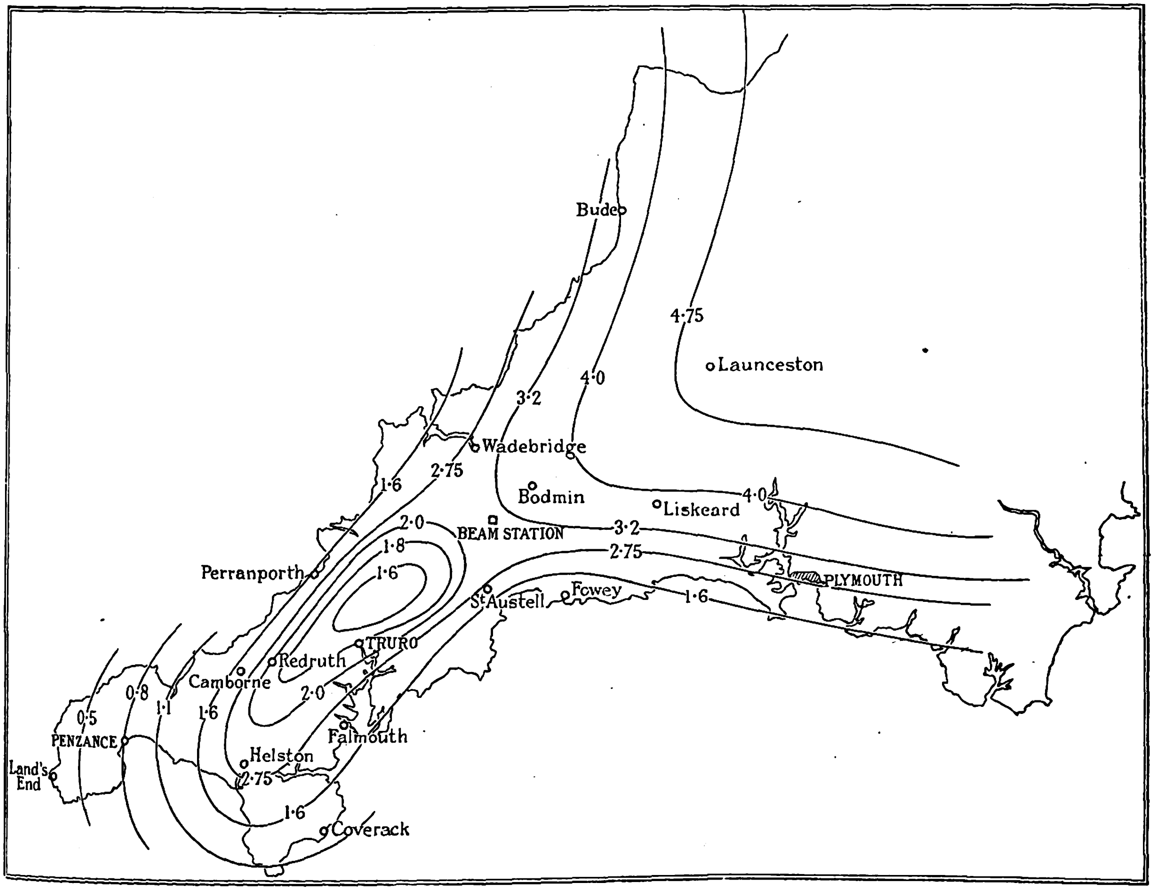

Fig. 3.—Final contours, showing shadow effect.

In every case the results obtained appeared to bear out the suggestion remarkably well, the final contours being shown in Fig. 3. On the north-east side of the Bodmin beam station the strength is of a normal order and in conformity with the contours shown in Fig. 2. At a point less than 10 miles to the south-west, however (on the other side of the Bodmin masts), the strength falls to approximately half its former value. Moreover, this region of bad reception extends in an almost direct line from Daventry through Bodmin as far as Redruth, a distance of nearly 25 miles.

A further interesting point is that surrounding this area of low signal strength is a ridge of good reception. Thus as one goes out towards the coast from a central point such as Truro, the signal strength rises on either side and then falls away rapidly towards the coast-line. What is perhaps more peculiar is that as one proceeds farther west the signal strength rises at first instead of falling and then subsequently attenuates very rapidly.

Particular care was taken to confirm this point in order to determine whether the ridge of high field-strength was maintained completely round the shadow area or whether it would be observed at the two sides only. Definite evidence of good signal strength, however, was found at such places as Helston and Camborne, both of which points lie on the theoretical contour line which one might expect. It appears, therefore, that this belt of good reception does actually exist immediately beyond the dead area around the Truro district.

The falling-off, once this high-field-strength ridge has been passed, is very rapid. In the short distance between Camborne and Penzance, for example, the signal strength falls to nearly one-third of its initial value, while the effects, already cited, of the very rapid drop in signal strength along the coast-line in such localities as Perranporth are also attributable to the same cause.

Whether the shadow effect is actually produced by the Bodmin masts is a point which can only be definitely confirmed by further experiments. There is, of course, the possibility that the curious configuration of the contours is due to mineral deposits. In order to obtain further information inquiries were made in various localities regarding any observed difference in the reception from 5XX after the erection of the Bodmin beam station. The station commenced operation some years ago and the information therefore is not reliable, but there is a distinct impression that the interference experienced during the reception of 5XX has been greater since the beam station was erected. Indeed, it is understood that representations were made to the Post Office to this effect when the station was first brought into commission, and investigations were made to see what interference was being produced by the beam station. No evidence of such interference was forthcoming and the matter was dismissed.

The suggested theory of a radio shadow, however, provides a satisfactory explanation. In certain districts the signal strength would fall considerably, in consequence of which the reception in those areas would be rendered more liable to interference from shipping and atmospherics, both of which are particularly troublesome in this part of England. The complaint of more interference, therefore, was apparently justified, but the nature of the interference was of a different character from what was anticipated.

(3) ANALYSIS OF RESULTS.

No detailed analysis of the results has been made, having regard to present-day theories of wave propagation. Certain check calculations have been made, however, which appear to indicate that the results are of the order to be expected. All readings, of course, were taken during the daytime, the period being the month of June 1929, and no readings were taken after 7 p.m. as it was felt that there might be danger of interference by the indirect ray at later times than this.

The first check calculation was the effective height of the 5XX aerial as deduced from the observed field strength at Elstree. As the distance from Daventry is 90 km there is little likelihood of serious attenuation. An estimate of the attenuation was made from Sommerfeld's formula and a figure of 4 per cent taken.*

On this assumption, the un-attenuated field strength at Elstree would be 13·0 millivolts per metre, approximately. Thus the effective height of the 5XX aerial, based on an assumption of 60 amperes aerial current, would be 80·5 m.† The 5XX masts are 164 m high, the aerial being of T shape and the down-lead being approximately 130 m high. In the light of these figures, the value of effective height appears to be eminently reasonable.

The second check was on the signal strength actually received in Cornwall as compared with the theoretical value calculated from the usual formula. In view of the distorted contours it is somewhat difficult to decide what shall be taken as the mean field strength at any given distance from Daventry. The wedge-shaped formation is also troublesome, for there are two ways of regarding this. One is to consider the strength at the peak as correct and to assume that the falling-away at the sides is due to some absorption effect produced at the coast-line. It is not quite clear how such an effect could arise. The second way of regarding the contours is to assume that the true contours are at the coast-line and that the extension of the contour towards the west inland is due to the Bodmin masts in a similar but opposite manner to the shadow effect on the other side of Bodmin. There appears to be some justification for this point of view because the attenuation deduced on the first assumption is very small, rather less, indeed, than that over sea water.

Probably the most satisfactory procedure is to take a mean value and this has been done in Table 1.

TABLE 1.

Comparison of Actual and Theoretical Field Strength.

Distance from 5XX	Theoretical field strength (un-attenuated)	Mean observed field strength	Ratio
km	mV/m	mV/m	per cent
280	4·18	3·8	90·5
305	3·81	3·2	84·0
335	3·5	2·5	71·5
360	3·27	1·6	49·0
385	3·04	0·8	26·3

It will be observed that up to 300 km the attenuation is fairly small but not unreasonably so, and the figures coincide approximately with the values obtained from Sommerfeld's theory. Beyond this point, however, the attenuation is increasingly rapid, and at Land's End, which is only 400 km away, the field strength is less than one-quarter of its theoretical value.

As was previously stated, this analysis is very rough and was intended merely as a check on the reasonableness of the figures obtained. The author has not had time nor is he sufficiently well acquainted with the formulæ to make a comprehensive analysis, but it is hoped that the results quoted will be of assistance to more qualified investigators in their endeavours to define the laws governing the propagation of wireless waves.

THE CAPACITY EFFECT AND NATURAL FREE PERIOD OF A DIRECT-CURRENT ARMATURE.[*]

By J. C. Prescott, Associate Member.

(*Paper first received 2nd April, and in final form 26th July,* 1929.)

Summary.

The analogy between the absorption of energy by a coil free to rotate in a constant magnetic field and the charging of an electrostatic condenser was pointed out by Swinburne[†] in 1902, and was again stated by Kapp in developing the theory of his vibrator.[‡]

The phenomenon of instability of direct-current shunt motors with interpoles was treated by Siebert,[§] Wagner,[||] Rosenberg[¶] and others, while the instability of differentially compounded motors was dealt with by Greeve[**] and Andrade.[††]

In the present paper the correspondence between electrostatic and "dynamical" capacities is re-stated in a somewhat different form, and the theory of the instability of compounded motors is developed as an extension.

A series of experiments is described, the results of which are cited as confirmation of the results obtained by the mathematical analysis, and, in the Appendix, details of the solution of certain of the equations are given.

List of Symbols.

$a, A, A', A'', b, B, B', \gamma$ = numerical constants.

$\alpha, \alpha', \alpha'', \beta, \beta'$ = constant angles (radians).

C = electrostatic capacity (farads).

E = e.m.f. (volts).

$\mathbf{I}$ = moment of inertia of armature (lb.-ft.^{2}).

i = instantaneous value of current (amperes).

i_f = armature current due to friction loss (amperes).

K = percentage change in induction factor.

k = stiffness of galvanometer suspension.

L = self-induction of armature (henrys).

M = induction factor.

n = number of parallel paths through armature.

p = number of pole-pairs.

Φ = flux per pole.

$\phi = \text{arc tan}\,\dfrac{abM^2}{R\mathbf{I}\omega}$.

R = resistance (ohms).

T = natural free period of armature (secs.).

$\mathbf{T}$ = torque (lb.-ft.).

t = time displacement from zero (secs.).

θ = mechanical displacement of armature (radians).

ω = angular velocity of e.m.f. vector (radians per sec.).

z = number of active conductors on armature.

Introduction.

As pointed out by Swinburne[*] and Kapp,[†] a coil free to vibrate in a magnetic field of constant strength reproduces, when subjected to an alternating e.m.f., the effects of a large capacity. It can be shown, however, that this capacity effect is also present when a direct e.m.f. is applied to the coil.[‡]

If we consider a direct-current armature whose induction factor[§] and resistance are M and R respectively, then

$$E = aM\frac{d\theta}{dt} + Ri \quad . \quad . \quad . \quad . \quad (1)$$

$$bMi = \mathbf{I}\frac{d^2\theta}{dt^2} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where E = applied e.m.f.,
i = current at any instant,
θ = mechanical displacement of the armature,
$\mathbf{I}$ = moment of inertia of the armature,
and a and b are constants.

This gives as a solution the exponential equation

$$i = \frac{E}{R}e^{-abM^2/(R\mathbf{I})} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

and may be compared with the conditions in a circuit containing electrostatic capacity C and resistance R. The current in this case is given by

$$i = \frac{E}{R}e^{-t/(CR)}$$

Inspection of equation (3) shows that the rate of decrease of current is reduced as R or $\mathbf{I}$ is increased, and suggests a method of facilitating the performance of the Kapp retardation test on machines of small moment of inertia[||] by adjusting the resistance in series with the armature to such a value that the rates of change of current and voltage are so low as to be easily observable. The equations become identical if the following substitution be made:—

$$CR = \frac{R\mathbf{I}}{abM^2}$$

or

$$C = \frac{\mathbf{I}}{abM^2}$$

[§] Induction factor = $2\Phi zp/(10^8 n)$, where Φ is the flux per pole, z the number of active conductors on the armature, p the number of pole-pairs, and n the number of parallel paths through the armature. The value of the induction factor is assumed to be constant except where otherwise stated.

[||] See G. Kapp: "The Principles of Electrical Engineering," vol. 2, p. 156 *et seq.*

Thus, in the dynamical case, $\mathbf{I}/(abM^2)$ may be termed the "equivalent capacity" of the circuit.*

The behaviour of the armature under the influence of an alternating e.m.f. may now be considered.

If we let ω represent the angular velocity of the e.m.f. vector, in radians per second, and t the time displacement from zero, in seconds, then the following equations must be satisfied:—

$$aM\frac{d\theta}{dt} + Ri = E \sin \omega t \quad . \quad . \quad . \quad (4)$$

$$\mathbf{I}\frac{d^2\theta}{dt^2} = bMi \quad . \quad . \quad . \quad . \quad . \quad (5)$$

which give as a solution, when the transient term has disappeared,

$$i = \frac{E \sin (\omega t + \phi)}{\left\{\left(\frac{abM^2}{\mathbf{I}\omega}\right)^2 + R^2\right\}^{\frac{1}{2}}}$$

where $\tan \phi = \frac{abM^2}{R\mathbf{I}\omega}$

Thus with increasing frequency the current through the armature will rise.

This may be compared with the equation for the current flowing under the influence of an alternating e.m.f. $e = E \sin \omega t$ in a circuit containing electrostatic capacity C and resistance R, namely,

$$i = \frac{E \sin (\omega t + \phi)}{\left\{\left(\frac{1}{C\omega}\right)^2 + R^2\right\}^{\frac{1}{2}}}$$

where $\tan \phi = \frac{1}{CR\omega}$

Thus it is seen that the equivalent capacity may still be represented by

$$C = \frac{\mathbf{I}}{abM^2}$$

It is perhaps of interest to compare the nature of this capacity with that of the electrostatic capacity. In the latter, energy is stored by the establishment of an electrostatic stress in the dielectric. In the former, the energy is stored kinetically in the rotating armature, which, if there were no losses in the coils or friction in the bearings, would continue to rotate after the removal of the e.m.f. from its terminals, thus maintaining itself in a state of charge, due to the presence of the kinetic energy of rotation, which energy could be abstracted by the establishment of electrical connection between the terminals.

An electrostatic capacity involves a strain in the dielectric; the dynamical capacity depends upon the velocity of the moving parts and upon their mass, and has, in electrostatic units, the dimensions of a length, for the induction factor varies directly as the flux. Therefore

$$C \propto \frac{\text{Moment of inertia}}{(\text{Flux})^2}$$

$$\propto \frac{(\text{Mass})\,(\text{Length})^2}{\left\{(\text{Length})^{\frac{1}{2}}\,(\text{Mass})^{\frac{1}{2}}\,\epsilon^{-\frac{1}{2}}\right\}^2}$$

$$\propto (\text{Length})\epsilon,$$

where ϵ is the specific inductive capacity.

The magnitude of C may be determined by inserting the values of a and b.

Thus, if $\mathbf{I}$ is in lb.-ft.², and θ (the mechanical displacement of the armature) in radians, equations (1) and (2) require that

$$a = 0 \cdot 159$$

and $b = 3 \cdot 76$

therefore $C = \frac{\mathbf{I}}{0 \cdot 596 M^2}$

Thus, for an armature with a moment of inertia of 100 lb.-ft.² and an induction factor of 37 (giving about 750 r.p.m. at 460 volts),

$$C = \frac{100}{0 \cdot 596 \times (37)^2} = 0 \cdot 124 \text{ farad}$$

THE EFFECT OF SELF-INDUCTION.

Since self-induction is, in general, present in a direct-current armature, the previous equations can only be taken as representing a special case.*

Let L be the self-induction of the armature; then if the latter be accelerated above its normal running speed, its motion may be represented by the equations

$$-aM\frac{d\theta}{dt} = Ri + L\frac{di}{dt} \quad . \quad . \quad . \quad . \quad (6)$$

$$bMi = \mathbf{I}\frac{d^2\theta}{dt^2} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

which give for θ three values depending upon whether $abM^2/(L\mathbf{I})$ is greater than, equal to, or less than $R^2/(4L^2)$.

In the two latter cases the solutions are of the exponential form, but the first solution is trigonometrical:

$$\theta = Ae^{-Rt/(2L)} \sin \left\{\left(\frac{abM^2}{L\mathbf{I}} - \frac{R^2}{4L^2}\right)^{\frac{1}{2}} t + a'\right\} \quad . \quad (8)$$

where A and a are constants.

This represents the damped harmonic vibration of a system the undamped free period of which is $\sqrt{[abM^2/(L\mathbf{I})]}$; and thus it is seen that, for certain values of M, L, R and $\mathbf{I}$, the direct-current armature has a natural free period of vibration the damping of which is directly proportional to the resistance of the circuit.

In this respect the mechanical oscillation is similar to an electrical one for, in a circuit containing a condenser of capacity C in series with a self-induction L having a resistance R,

---

* Cf. expression obtained by Kapp in the theory of the vibrator. [See Bibliography (6).]

* See Bibliography, (11).

$$i = A''e^{-Rt/(2L)} \sin\left\{\left(\frac{1}{CL} - \frac{R^2}{4L^2}\right)^{\frac{1}{2}} t + a''\right\}$$

This may be compared with the vibration of a moving-coil galvanometer, having a coil of induction factor M connected across a non-inductive resistance R, the stiffness of the suspension being k.

The equation of motion is

$$\mathbf{I}\frac{d^2\theta}{dt^2} + \frac{abM^2}{R} \cdot \frac{d\theta}{dt} + k\theta = 0$$

and the solution when $\frac{k}{\mathbf{I}} > \frac{a^2b^2M^4}{4R^2\mathbf{I}^2}$ is

$$\theta = A'e^{-abM^2/(2R\mathbf{I})t} \sin\left[\left\{\frac{k}{\mathbf{I}} - \left(\frac{abM^2}{2R\mathbf{I}}\right)^2\right\}^{\frac{1}{2}} t + a'\right]$$

where A' and a' are constants. In this case the damping is inversely proportional to R.

CONDITIONS FOR OSCILLATION.

In order that oscillation may be possible, it is necessary that $R^2/(4L^2)$ shall be less than $abM^2/(L\mathbf{I})$; that is, R and $\mathbf{I}$ must be small and M and L large. $\mathbf{I}$ will in general depend upon the diameter of the armature, and for large machines, at voltages up to 500, $abM^2/\mathbf{I}$ will be comparatively small. Thus, in order to achieve the oscillating condition, L must be made large and the natural free period

$$T = 2\pi\sqrt{\left(\frac{L\mathbf{I}}{abM^2}\right)}$$

must of necessity be high.*

It is therefore unlikely that free periods of oscillation lower than 2 or 3 seconds will be encountered in practice, but that this free period may exist is shown by the equations above and by oscillograms which are reproduced later in the paper (see " Experimental Work ").

FORCED VIBRATIONS.

Since the armature, when self-induction is present, exhibits an inherent free period, it is reasonable to expect that the displacement should vary with the frequency of an applied disturbance, reaching a maximum as this frequency approaches the resonant frequency of the armature.

The equations of forced vibration under a varying voltage may be written

$$aM\frac{d\theta}{dt} + L\frac{di}{dt} + Ri = E \sin \omega t \quad . \quad . \quad (9)$$

$$\mathbf{I}\frac{d^2\theta}{dt^2} = bMi \quad . \quad . \quad . \quad . \quad . \quad (10)$$

which give as a solution, when the transient term has disappeared,

$$\theta = \frac{bME \sin(\omega t + a)}{\omega\left\{(L\mathbf{I}\omega^2 - abM^2)^2 + (R\mathbf{I}\omega)^2\right\}^{\frac{1}{2}}} \quad . \quad (11)$$

and

$$i = -\frac{E\mathbf{I}\omega \sin(\omega t + a)}{\left\{(L\mathbf{I}\omega^2 - abM^2)^2 + (R\mathbf{I}\omega)^2\right\}^{\frac{1}{2}}} \quad . \quad (12)$$

where

$$\tan a = \left(\frac{abM^2 - L\mathbf{I}\omega^2}{R\mathbf{I}\omega}\right)$$

θ will reach a maximum for $\omega = 0$, and, if R is small, will have a second maximum at $\omega \approx abM^2/(L\mathbf{I})$; while if R is near to its second critical value,* the second maximum will occur at $\omega = abM^2/\left\{(\sqrt{3})L\mathbf{I}\right\}$. The current will, however, have only one maximum, which will occur at $\omega = abM^2/(L\mathbf{I})$, irrespective of the magnitude of the resistance.

For this value of ω,

$$i = \frac{E}{R} \sin \omega t$$

imitating the condition of resonance for a circuit containing inductive resistance and electrostatic capacity.

The condition examined above would correspond to the case of a motor supplied with a periodically fluctuating voltage, but forced vibrations may also be set up by fluctuations in the torque demanded of the motor. If the torque be represented by

$$\mathbf{T}' = \mathbf{T} \sin \omega t$$

this condition can be defined by the equations

$$aM\frac{d\theta}{dt} = L\frac{di}{dt} + Ri \quad . \quad . \quad . \quad . \quad (13)$$

$$\mathbf{I}\frac{d^2\theta}{dt^2} + bMi = \mathbf{T} \sin \omega t \quad . \quad . \quad . \quad . \quad (14)$$

which give, as a solution for θ,

$$\theta = \frac{\mathbf{T}\sqrt{(R^2 + L^2\omega^2)} \sin(\omega t + \phi)}{\omega\left\{(L\mathbf{I}\omega^2 - abM^2)^2 + (R\mathbf{I}\omega)^2\right\}^{\frac{1}{2}}}$$

and for i,

$$i = \frac{\mathbf{T}}{M}\left\{1 + \frac{\omega\sqrt{(R^2 + L^2\omega^2)}}{\left\{(L\mathbf{I}\omega^2 - abM^2)^2 + (R\mathbf{I}\omega)^2\right\}^{\frac{1}{2}}}\right\} \sin(\omega t + \phi)$$

which, if R is small, has a maximum at

$$\omega \approx \frac{abM^2}{L\mathbf{I}}$$

INSTABILITY.

If the direct-current armature rotate in a compounded field, the motion may be unstable if the compounding is such as to weaken the field for an increase in motoring current.† If K is the percentage change in the induction factor for unit current in the series field, the equations of motion may be written

$$E = a(M - Ki)\frac{d\theta}{dt} + Ri + L\frac{di}{dt} \quad . \quad . \quad (15)$$

$$\mathbf{I}\frac{d^2\theta}{dt^2} = bi(M - Ki) \quad . \quad . \quad . \quad . \quad (16)$$

---

* See Appendix.

See Appendix.

† See Bibliography, (11).

the exact solution of which is a matter of considerable mathematical difficulty. If, however,

$$(KE - RM) < \frac{4abM^4L}{I}$$

approximations may be employed to give

$$i = Be^{-\gamma t}\cos(\delta t + \beta) \quad . \quad . \quad . \quad (17)$$

where

$$\gamma = \frac{RM - KE}{2ML}$$

$$\delta = \sqrt{\left\{\frac{abM^2}{LI} - \left(\frac{RM - KE}{2ML}\right)^2\right\}}$$

and B and β are constants.

$$\frac{d\theta}{dt} = \frac{1}{aM}\left\{E - B'e^{-\gamma t}\cos(\delta t + \beta')\right\} \quad . \quad (18)$$

where B' and β' are constants.*

Thus it is seen that if KE/M is greater than R the index of e is positive, and the amplitude of the vibrations of current and velocity increases with time after the initial disturbance, an increasing harmonic vibration being set up. Inspection of equation (15) confirms this result, for it is seen that, for certain values of K, $d\theta/dt$ and R, the term $K \cdot d\theta/dt$ may be greater than R and $i(R - Kd\theta/dt)$ may have a negative value for a positive (i.e. motoring) current; thus, in effect, a negative resistance is introduced into the circuit and may be expected to induce instability. The value of this negative resistance for given values of R and K will depend on $d\theta/dt$, and thus a certain critical speed will exist above which the machine will become unstable, and below which instability will not appear.

EXPERIMENTAL WORK.

In order to confirm the results of the mathematical investigation, a series of measurements was made on direct-current machines in the Laboratories of Applied Electricity at the University of Liverpool.

One phase of the armature of a Schrage commutator motor was used to give an alternating e.m.f. of low frequency. This type of motor has many advantages when used as a frequency changer; the frequency of the voltage appearing at the brushes is continuously variable from zero, with the armature rotating at synchronous speed, to supply frequency, with the armature at rest; the voltage at the brushes depends only on their "spread" (which is adjustable) and is independent of the armature speed; and the wave of voltage is practically free from harmonics.

In the first series of experiments the armature of the Schrage motor was connected to the armature of the direct-current machine under test. The Schrage motor was excited with current at a frequency of 50 cycles per sec. from the mains and was driven by a direct-current motor at a speed approximating to the synchronous speed. In order to compute the periodicity at the brushes, an integrating device was used which consisted of a clock mechanism from which the balance wheel had been removed, and the escapement of which was operated by means of an electromagnet connected in series with a non-inductive resistance across the brushes of the Schrage motor (Fig. 1). A pointer attached to the escapement wheel made one complete revolution for 50 cycles at the brushes, and thus, by timing a whole or partial revolution by means of a stop-watch, the frequency could be directly measured.

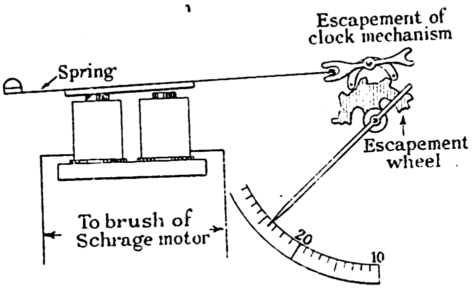

FIG. 1.

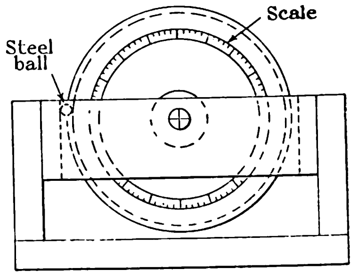
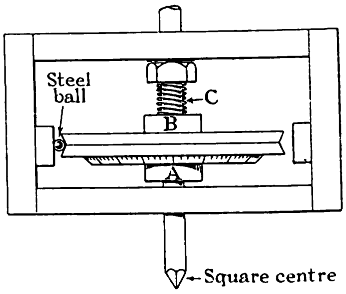
For observing the angular deflection of the direct-current armature, the device shown in Fig. 2 was used. It consists of an ebonite wheel in the edge of which is cut a V-shaped groove. This wheel is driven from the shaft by the friction of the collars A and B, one of which is rigidly fixed to the shaft while the other acts as a washer to transmit the pressure of the spring C. The frame of the instrument is provided with two vertical plates at a distance of $\frac{1}{16}$ in. from the wheel. When observing the angular displacement, a small steel ball was placed between the grooved rim of the wheel and the plate; thus the wheel was free to rotate with the shaft in one direction, but, due to the binding of the ball between the wheel and the plate when the shaft rotated in the opposite direction, the wheel



Elevation



Plan

FIG. 2.

---

* See Appendix.

slipped between the collars and progressed in one direction only.

A graduated scale attached to the wheel enabled the total progression for a given number of oscillations of the armature to be observed. Thus the amplitude of the swing could be determined. Since the displacement of the armature on either side of the mean position was not always the same, observations of the displacement in both directions were taken by moving the ball from one side of the wheel to the other.

— ·· — Deflection (degs.). Self-induction = 0·115 H.
(Calculated points shown ×).
Constant applied p.d. = 5 volts.

In making the measurements, a hot-wire ammeter was placed between the direct-current motor under test (the field of which was maintained at a constant value) and the Schrage motor (see Fig. 3). Readings of armature current and frequency were taken with various amounts of self-induction in series with the direct-current armature.

Examples of the curves obtained at constant voltage are shown in Fig. 4, in which, also, the displacement of the armature, both calculated and observed, is plotted against frequency. It is seen that, although the current through the armature reaches a definite maximum in each case, the deflection decreases as the frequency rises, since the resistance in the circuit (viz. 2 ohms) was greater than the second critical resistance for the machine. A definite point of inflection, however, appears on the deflection curve at a point somewhat below the point of resonant frequency on the current curve.

In calculating the displacement, the formula

$$bM(i - i_f) = \mathrm{I}\frac{d^2\theta}{dt^2}$$

was used, which gives, assuming a sinusoidal current wave-form,

$$\theta_{max.} = \sqrt{2}\left\{\frac{bM}{\mathrm{I}\omega^2}(i - i_f)\right\}$$

where i_f is the friction current of the machine, which is assumed constant and which in the machines under test was 1 ampere. The results of these tests are given in Table 1.

NOTE: ω_r is 2π times the frequency at which current resonance occurs.

To show the swing of the direct-current machine graphically, a shunted Einthoven galvanometer was used. The machine was run up to speed as a motor, and when steady conditions had been obtained the supply was interrupted for a short period. The oscillations of current on the re-establishment of the supply were recorded photographically by the galvanometer.

In Fig. 6, brushes rocked 1 segment back to give, with the compounding, $KE > RM$.

Examples of the records obtained with various degrees of compounding on the motor are shown in Figs. 5 and 6.

CONCLUSION.

The author wishes to express his thanks to Dr. E. W. Marchant, Member, for much encouraging criticism and advice; and to Mr. U. S. Haslam-Jones, M.A., for the mathematical treatment of the "second critical resistance" and for the solution (much more elegant than that obtained by the author) of the equation for the compounded motor.

APPENDIX.

The Starting Current of a Direct-Current Armature on Constant Voltage.—The equations that must be satisfied are

$$E = aM\frac{d\theta}{dt} + R(i + i_f)$$

$$bMi = \mathbf{I}\frac{d^2\theta}{dt^2}$$

where i is the current required for acceleration and i_f the current required to supply the losses. This latter is, as an approximation, assumed to be constant. These equations can be combined to give

$$E = aM\frac{d\theta}{dt} + \frac{R\mathbf{I}}{bM}\frac{d^2\theta}{dt^2} + Ri_f \quad . \quad . \quad (18a)$$

where $d\theta/dt$ is the angular velocity of the armature. Integrating, we obtain

$$\frac{d\theta}{dt} = \frac{1}{aM}(E - Ri_f)\left\{1 - e^{-abM^2t/(R\mathbf{I})}\right\}$$

Substitution for $d^2\theta/dt^2$ in equation (18a) gives

$$i = \left(\frac{E}{R} - i_f\right)e^{-abM^2t/(R\mathbf{I})}$$

If $\quad E = e_0$ when $t = 0$

then $\quad i = \dfrac{E - e_0}{R}e^{-abM^2t/(R\mathbf{I})}$

Second Critical Resistance of a Direct-Current Armature.—In order that the armature may exhibit a free period, the auxiliary equation of

$$L\mathbf{I}\frac{d^2\theta}{dt^2} + R\mathbf{I}\frac{d\theta}{dt} + abM^2\theta = 0$$

must have unreal roots. That is to say, the radical $\sqrt{\left(\dfrac{R^2}{4L^2} - \dfrac{abM^2}{L\mathbf{I}}\right)}$ must be imaginary.

The first critical resistance will therefore be

$$R = \sqrt{\left(\frac{4LabM}{\mathbf{I}}\right)}$$

When the armature is subjected to a periodic potential difference, the following equation must be satisfied:

$$L\mathbf{I}\frac{d^2\theta}{dt^2} + R\mathbf{I}\frac{d\theta}{dt} + abM^2\theta = bME\sin\omega t$$

which gives as a solution

$$\theta = \frac{bME\sin(\omega t + a)}{\omega\left[(L\mathbf{I}\omega^2 - abM^2)^2 + (R\mathbf{I}\omega)^2\right]^{\frac{1}{2}}}$$

This will reach a maximum for $\omega = 0$, and for certain values of R there will be a second maximum. Thus, θ will reach a maximum when

$$\omega^2\left\{(L\mathbf{I}\omega^2 - abM^2)^2 + (R\mathbf{I}\omega)^2\right\}$$

is a minimum.

Differentiating this expression with respect to ω and equating to zero, we obtain

$$3\mathbf{I}^2L^2\omega^4 + 2\mathbf{I}\omega^2(R^2\mathbf{I} - 2abM^2L) + a^2b^2M^4 = 0 \quad (19)$$

When ω^2 is small this is positive, so θ decreases; also when ω^2 is large this is positive, so θ decreases. Thus θ either decreases steadily or has a minimum and a maximum value in the range.

In order that there may be a real critical value of θ it is necessary and sufficient that the roots of equation (19) should be real and positive; that is

$$(R^2\mathbf{I} - 2abM^2L)^2 > 3L^2a^2b^2M^4$$

$$R^2\mathbf{I} - 2abM^2L < 0$$

These may be combined to give

$$2abM^2L - R^2\mathbf{I} > \sqrt{3}LabM^2$$

$$R < \sqrt{\left\{\frac{(2 - \sqrt{3})abM^2L}{\mathbf{I}}\right\}}$$

This may be termed "the second critical resistance," since it is that resistance above which no second maximum appears in the curve of armature displacement plotted against frequency of disturbance.

The Current Equations for a Compounded Motor.—For a motor in which an increase in current causes a reduction in the strength of the main field,

$$E = a(M - Ki)\frac{d\theta}{dt} + Ri + L\frac{di}{dt} \quad . \quad . \quad (15)$$

$$\mathbf{I}\frac{d^2\theta}{dt^2} = bi(M - Ki) \quad . \quad . \quad . \quad . \quad (16)$$

where K is a factor depending upon the degree of the compounding.

Differentiating equation (15) and combining with equation (16) gives

$$\frac{KE - RM}{(M - Ki)^2}\frac{di}{dt} = \frac{ab}{\mathbf{I}}i(M - Ki) + \frac{L\,.\,d^2i/dt^2}{(M - Ki)} + \frac{LK(di/dt)^2}{(M - Ki)^2}$$

If K and L are small, this equation may be solved for small values of the current by neglecting KL and Ki; thus

$$ML\frac{d^2i}{dt^2} - (KE - RM)\frac{di}{dt} + \frac{abM^3}{\mathbf{I}}i = 0$$

which, if $(KE - RM)^2 < \frac{4abM^4L}{\mathbf{I}}$, gives

$$i = Be^{-\gamma t}\cos(\delta t + \beta)$$

where $$\gamma = \frac{RM - KE}{2ML}$$

$$\delta = \sqrt{\left(\frac{abM^2}{L\mathbf{I}} - \frac{RM - KE}{4M^2L^2}\right)}$$

and B and β are constants.

A READY METHOD OF MEASURING THE VOLTAGE RATIO AND PHASE ANGLE OF HIGH-VOLTAGE TRANSFORMERS.[*]

By G. YOGANANDAM, B.E., Graduate.

(*Paper first received* 21*st February, and in final form* 27*th May,* 1929.)

SUMMARY.

A quick and ready method of measuring the ratio and phase angle of high-voltage transformers is described in which the well-known high-voltage Schering bridge is employed. Formulæ for the voltage ratio and phase angle are given, together with expressions for the sensitivity of the bridge. The accuracy obtained by the method meets the requirements of all industrial tests as well as of research work.

INTRODUCTION.

In 1927 a method of measuring the ratio and phase difference of high alternating voltages was described by B. G. Churcher.[†] Though it is the only simple and accurate method so far known, yet, in the present author's opinion, it is not quite suitable for routine testing in its existing form. The present method makes use of the entire apparatus that is available in all manufacturing firms and high-voltage laboratories and is commonly known as the high-voltage Schering bridge.

METHOD OF MEASUREMENT.

In the case of a high-voltage transformer taking its supply on the high-tension side, the high- and low-tension windings are connected in opposition as indicated by the arrows in Fig. 1, and the junction of the windings is earthed. The other terminal of the low-tension winding is connected to one end of a good quality, variable mica condenser, which can withstand the voltage of the low-tension coil. The other end of the condenser is connected to the terminal marked "Test" in the bridge box PQRS (Fig. 1). The remainder of the connections are the same as those for testing cables or insulators. The condenser C is set to a value such that its ratio to the capacity of the standard condenser S (100 $\mu\mu$F) is approximately equal to the nominal ratio of the transformer. Then R_3 and C_4 are adjusted until balance is obtained. The connections of the terminals marked "Test" and "Standard" have to be interchanged if balance is not obtained with the circuit shown in Fig. 1. At balance, the resistances R_3 and R_4 are nearly equal, the latter being generally a fixed resistance of 1 000/π ohms.

FORMULÆ FOR RATIO AND PHASE ANGLE.

Fig. 2 gives the vector diagram of the circuit shown in Fig. 1.

Let

V and v = high-tension and low-tension voltages respectively,

ϕ = phase angle between them,

C = setting of the condenser C,

δ = loss of angle of the condenser for the particular setting C,

θ = phase angle between the currents i_1 and i_2 in the condensers S and C respectively [θ (at balance) = arc tan $\omega C_4 R_4$],

γ = phase angle between v and v_c, the voltage across the condenser C,

$\omega = 2\pi f$, f being the frequency,[*]

v_3 and v_4 = voltages across R_3 and R_4 respectively.

Referring to Fig. 2, OB is the low-tension p.d. lagging behind the high-tension p.d. OA by an angle ϕ which will be taken as positive. The current i_1 leads the high-tension p.d. V by an angle $90-\delta'$

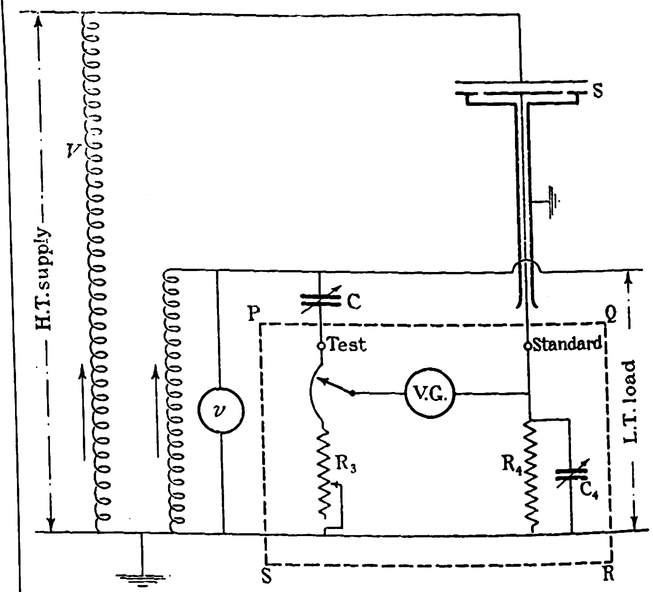

FIG. 1.

where
$$\tan \delta' = \frac{\omega S R_4 \cos^2 \theta}{1 + \omega S R_4 \sin \theta \cos \theta}$$

The voltages v_3 and v_4, which at balance are equal and in phase with the current i_2, are represented by OC.

[*] The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

[†] *Journal I.E.E.*, 1927, vol. 65, p. 430.

[*] In this paper it is assumed that $f = 50$.

From Figs. 1 and 2 we have

$$v_4 = V\frac{\sin\delta'}{\cos\theta}$$

and

$$v_3 = \frac{v}{\left\{1 + \frac{\cos^2\delta}{\omega^2C^2R_3^2} + \frac{\sin 2\delta}{\omega CR_3}\right\}^{\frac{1}{2}}}$$

Putting $v_3 = v_4$ and simplifying, we get

$$R = \frac{V}{v} = \frac{\omega CR_3 \cos\theta \operatorname{cosec}\delta'}{\left[\cos^2\delta + \omega^2C^2R_3^2 + \omega CR_3 \sin 2\delta\right]^{\frac{1}{2}}} \quad . \quad (1)$$

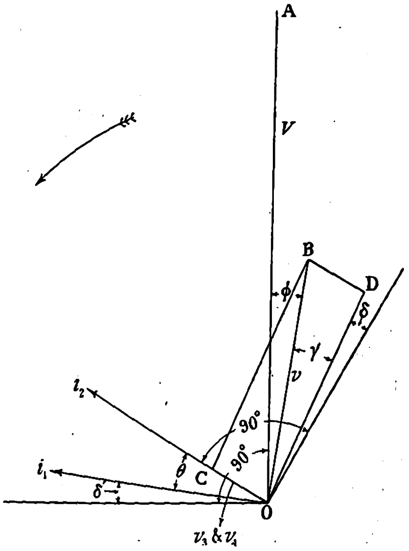

FIG. 2.

If δ' is sufficiently small to justify writing $\sin\delta' = \omega SR_4 \cos^2\theta$, and if in addition $C \not> 0{\cdot}5\,\mu$F and $\sin\delta \not> 0{\cdot}0005$, equation (1) can be rewritten

$$R = \frac{CR_3 \cos\gamma}{SR_4 \cos\theta} \text{ (approx.)} \quad . \quad . \quad . \quad . \quad (2)$$

where $\tan\gamma = \omega CR_3$ (approx.).

Also $$\phi = \theta + \delta' - \gamma - \delta \quad . \quad . \quad . \quad . \quad . \quad (3)$$

From (3) it is seen that the maximum negative phase angle that can be measured by the circuit shown in Fig. 1 is $\gamma + \delta - \delta'$. For larger negative angles, with the change of connections mentioned above, R and ϕ are given by

$$R = \frac{CR_4 \cos\theta}{SR_3} \times \frac{1}{\left[1 + \omega^2C^2R_4^2 \cos^2\theta + \omega CR_4 \sin 2\theta\right]^{\frac{1}{2}}} \text{ (approx.)} \quad (4)$$

and $$\phi = \theta - \delta' + \gamma + \delta \quad . \quad . \quad . \quad . \quad . \quad (5)$$

where

$$\sin\gamma = \frac{\omega CR_4 \cos^2\theta}{\left[1 + \omega^2C^2R_4^2 \cos^2\theta + \omega CR_4 \sin 2\theta\right]^{\frac{1}{2}}} \text{ (approx.)}$$

and $\tan\delta' = \omega SR_3$.

In deriving the above expressions the following additional assumptions have been made:

(1) That the effect of stray electric fields is negligible. This is true if all the apparatus except the transformer under test and the standard condenser are kept in an earthed metal enclosure.

(2) That the total capacity in parallel with R_3 or R_4, due to safety gaps and earthed screens, produces a negligible error in the ratio and phase angle. The total capacity does not generally exceed 400 $\mu\mu$F and can be neglected.

(3) That the effect of that portion of the slide wire (Fig. 1) which is in series with the condenser C is negligible.

EXPRESSIONS FOR SENSITIVITY.

For a change of 1 in 10 000 parts in the ratio or of 0·0001 radian of phase angle, the galvanometer deflection is given by

$$d = \frac{v\omega CR_4S \times 10^6}{10^4\left\{(2R_4 + R_g)^2 + \omega^2L_g^2\right\}^{\frac{1}{2}}} \text{ mm (approx.)} \quad (6)$$

where S is the sensitivity of the galvanometer in mm per microampere and R_g and L_g are the constants of the galvanometer coil. Taking the example of a 220/110 000-volt testing transformer, the value of C is 0·05 μF. Now putting $\omega = 314$, $R_4 = 320$ ohms, $R_g = \omega L_g = 250$ ohms (approximately), and $S = 30$ mm, the value of d at half the rated voltage of the transformer is found to be 1·8 mm. In industrial testing a sensitivity of one-tenth of the above amount would be sufficient and there would be no difficulty in obtaining consistent balance in practice. The present sensitivity is, however, also possible in practice if care is taken to keep the supply voltage and frequency constant.

ADDRESS TO THE LONDON STUDENTS' SECTION

By A. H. RAILING, D.Eng., Member.

"THE PHILOSOPHY OF ENGINEERING."

(*Address delivered* 19*th April*, 1929.)

Two ways were open to me in choosing the subject for this Address. The first way was to select some technical subject arising out of my everyday work, such as heavy engineering, factory management or administration, a lecture giving my audience some facts which might prove helpful to them in their own careers. Naturally, such a subject would be specialized, appealing, like most purely technical subjects, only to a fraction of the audience. The second possibility was to choose some personal message, something which could not be read in textbooks, something which would convey to you the angle from which the speaker views his profession, which is also yours. I have chosen the second, because I consider that the ordinary Institution lectures provide you with sufficient technical data, and because I feel that it will interest you more to learn how I regard the broad aspect of the electrical engineering profession in its relation to the affairs of humanity, and how my outlook has from time to time helped me to maintain correct perspective and preserve enthusiasm in my everyday work.

The mainsprings of a happy life—and that means a successful life—are character, knowledge, and imagination. The first is largely a gift of the gods, in part inherited from ancestors. The second and third presuppose the ability to assimilate other people's experience and points of view. But these points of view require elucidation and comparison. It is to your imagination that I wish to appeal specially in this address.

My subject, if it has no very practical issue, is yet most intimately connected with one's whole outlook on life and the ideals underlying it. You have selected for various reasons the engineering profession for your life's work; perhaps because, as somebody once confessed to me, "I cannot think of anything else to study"; or because your parents thought—wrongly, I am quite sure, as you will find out for yourselves—that it is easy to make a lot of money in the profession; or—and this is the best reason of all—because you felt instinctively drawn to it. You are now engaged in getting together the tools for your life's work, and when you start in earnest to apply them the mainsprings of your activity will be the anxiety to earn a living, to get on, to prove successful, to become a real power, to rule others. Now, either you will succeed in these endeavours, or you will fail; either, through hard work and constant application, through innate ability or good luck, you will rise from the ranks to the top, or you will be destined to remain in the ranks. But, whichever is the case, the day will come when routine work will become monotonous (and there is routine work even in the highest positions); when the initial glory of achievement will pale, when you will reach the point of asking yourself what sense is there in all this work, what satisfaction beyond a livelihood or a piece of cheap self-satisfaction; when you will ask yourself whether you would not have done better in theology or law or as a doctor. When this day comes, unless you visualize and appreciate the part which you and the engineering profession are playing in the world, unless you realize that, whatever your individual part, you are a unit in one of the greatest forces in the general scheme of progress of humanity, your work cannot be really satisfying, for no life can be really happy unless the worker feels that whatever latent energy is in him has been translated into dynamic energy as a contribution, be it ever so small, to a community, to a general scheme.

The object of this Address is to provide you with a few thoughts, more or less at random, which illustrate the position that our profession holds in this general scheme of mankind, what the pioneers in our profession have done in the past, and the road which we have to travel in the future. If you grasp the sense and meaning of our profession in this light, you will possess something that will enable you to see the situation in true perspective, even when you are engaged in pure routine work.

Consider the various professions. Theology has taught man the laws of ethics and morals, and his relation to that higher Power which is both within and without. The legal profession has taught him the rights and duties of one individual against another, one class against another, one race against another; it has taught him to supplant brute force by order. The medical man has studied the functions of man's organisms and the laws which govern their actions, in an endeavour to apply these laws for man's physical betterment. The field of the engineer is a realm apart from living organisms; it ranges from planets to atoms, with their infinite variety of combinations, energies, and applications in the service of mankind. It is materialistic, the older professions often say. Yes; but the basis of everything, including men and, *ipso facto*, their professions, is idealistic, because it is only the knowledge that we possess to-day which can give us a proper understanding of the world and mankind, and their purpose, thereby leading to the possibility of further progress.

Let us look first at the historical facts of the past. What has been achieved by engineering, regarding the profession in the light of the definition I have just given? You will not expect this subject to be exhausted in this Address; I can dwell on a few aspects only, and since we are all electrical engineers you will forgive me if my picture is coloured in that direction. That which applies to electrical engineering in particular applies to all branches of engineering in general.

As man emerged from the age when he was merely a hunter there followed the development of the nomad tribe who kept cattle instead of hunting animals. Later came the tiller of the soil; then, on account of the sedentary method of living, successively, the builder of homesteads, the priest caste, the medicine man, the lawgiver, and so forth. All these vocations have already been in existence for thousands of years. Why has engineering, and especially electrical engineering, come so late, and what is its mission? As humanity progressed, it dealt with men and matter as it found them, and it used the kinetic energy of men and animals, and perhaps of wind and water, as well as certain known substances and some of their physical properties. Attempts were made from time to time to probe deeper, but practically nothing was known of the structure of matter, or of energy in its manifold variations, until a comparatively short time ago. The problems of dynamics, if we leave out Aristotle, were dead until the time of Galileo and Newton; the problems of matter, until Priestley and Berzelius. Engineering science meant, as in Galileo's law, going away from this earth to other worlds, or, as in the atomic theory, going deeper and deeper into the infinitesimal.

Electrical engineering started when humanity was prepared for an advance in this direction. In its narrower sense it means the application of the knowledge of what we call "electricity." In its broader sense, it embraces to-day all knowledge of matter and its attribute "energy," or vice versa, energy which manifests itself in the form of matter and its applications.

If we consider the history of the progress of the knowledge of matter, the sequence is a logical one. First, laws were discovered dealing with the physical properties of matter, of measurable bodies which we could see; later, with the properties of the invisible molecule, which was already a theoretical conception; later still, with those of the atom; and now, with those of the electrons, proceeding step by step to smaller and smaller units.

If, on the other hand, we consider the history of the progress of the knowledge of motion, we find exactly the same development from Galileo's and Keppler's law of the planets to the knowledge of the potential and kinetic energies of moving visible bodies, of heat and cohesion; the energy of the molecule to chemical energy, the energy of atoms, and thence to the knowledge of electricity and light and the energy of corpuscles as the basis of all. The knowledge of all these problems and the application of such knowledge went hand in hand, sometimes practice leading and theory following, sometimes theory first and practice afterwards; and it is self-evident that the sequence depended partly on the demand for practical applications to aid human need, the desire to achieve something, or, on the other hand, the mental craving to understand the fundamentals underlying certain established facts and, by understanding them, gradually to govern them.

I have tried here to show how and why engineering, and especially electrical engineering, came as the latest revelation of visible matter, and of the energy of visible matter, leading further and further into the region of the invisible and infinitesimal.

Having shown the path leading to our profession, I now come to the second point. How far has engineering, and especially electrical engineering, already contributed to human development by improving human progress and efficiency? The following are some of its contributions:

(1) Our profession enables us to make better use of matters by increasing the number of varieties in existence, by producing these more cheaply, and by making better use of their properties.

(2) It enables us to make better use of all the available forms of energy.

(3) It increases the space that can be inhabited and made use of by man.

(4) It increases the physical and mental power and efficiency of each individual of the whole human race.

(5) In addition to increasing the efficiency of the individual, it increases the efficiency of the whole human race, increasing either the average efficiency or the total efficiency.

The proof of what has been achieved could be given in innumerable ways. One could relate the romance of materials; how man passed from the Stone Age, when he knew of no metals, to the Iron and Bronze Ages, until to-day he has knowledge of over 80 elements and of thousands of combinations, each one of which combinations he can produce at will out of the elements, each one of which elements he can reduce out of certain composite bodies. One could relate the story of transport, from the building of roads on terra firma and the discovery of the wheel, to the hundreds of thousands of miles of railway laid and motor-cars built; or the story of transport on water, from the boat burnt out of a hollow tree, to the galley, to the sailing boat and steamer, and thence to the oil engine, turbine, and electrically driven monsters of to-day. One could tell of the submarine, and the conquest of the air, or a hundred and one other achievements.

From a philosophical point of view—which means a natural science point of view—engineering, and especially electrical engineering, is the most potent factor in the increase of mankind's efficiency for the five reasons which I have just stated, and to which I will now refer in rather more detail.

(1) *Electrical engineering enables us to make better use of matter by increasing the number of varieties in existence, by producing these more cheaply, and by making better use of their properties.* You know of the electro-deposition of metals, of the electrolytic processes and of the reduction processes. To mention a few examples, a new metal, aluminium, has been given to us by electric reduction of kaolin; electrolytic copper, of which 42 000 tons were produced in 1870, has by electrical processes risen to a production of 1 400 000 tons in 1920. The production of gold by the cyanide process, of lead and zinc from low ores, of oxygen and hydrogen for the bleaching of cotton and paper, of caustic soda, of nitrogen from the air for fertilizers; these and many other examples which could be cited show what has been done during the last 30 years. Think of the values created, of

the avenues of progress opened and of the results achieved.

(2) *Electrical engineering enables us to make better use of all the available forms of energy.* We have in successive steps arrived at the knowledge that energies are restricted to and based on one, and only one, electric energy. All other energies are merely variations—radiation, the energy of accelerated corpuscles; chemical energy, the energy of groups of corpuscles called atoms; heat, the energy of groups of atoms called molecules; mechanical energy, the energy of molecules grouped in measurable volumes.

We have thus acquired the knowledge that energy does not exist apart from matter, but is its attribute; one form of energy can be converted into another. What is the result? Most, if not all, of the energy of this planet is derived from the heat and radiation energy of the sun. Most energy available from this source is available either in the form of kinetic energy in rivers and the tides of the sea, or in the chemical energy of coal, oil and other organic substances. We take this energy wherever we find it, use it in our prime movers, transform it into mechanical energy, re-transform it in our dynamos into electrical energy and, since this electrical energy is more easily and efficiently transported than any other form of energy, we transmit it for hundreds of miles to places where we require it. Now energy is required in the form of light, heat, mechanical and chemical energy, and since electrical energy is not only the easiest to transmit but is also the easiest to convert, we re-convert the current into light, into heat, into mechanical energy, thereby enabling the efficient working of mines, factories, steelworks, mills, trains, lifting machinery, and a thousand industrial applications. Thus electrical energy has annihilated space. But it has annihilated time as well. Whereas in tropical countries during monsoon time the kinetic energy of water ran to waste, we now collect it in the mountains by damming it up. How these achievements should appeal to the imagination! For instance, hundreds of miles from Bombay sufficient water is collected during the monsoon period to drive for the whole year the cotton mills of that city, requiring 100 000 kW.

Two years ago I travelled over the plains of Palestine, once a fertile country, now waste on account of lack of the power necessary to pump water for irrigation purposes; and I stood at Lake Tiberias with another man, developing the scheme which is now under construction for collecting the water that comes into that basin during 4 weeks, and which is sufficient to provide power for a country for irrigation and industry for 12 months.

(3) *Electrical engineering increases the space that can be inhabited and made use of by man.* It is already clear from the previous section that certain materials which can now be produced by electricity could not have been produced without it, since it would have been too costly to transport the raw materials to the available sources of energy, or to bring the energy to the raw materials. But, further, given a definite number of human beings the increased rapidity of locomotion which engineering, and especially electrical engineering, has produced has the effect of decreasing distances, thus increasing the radius of action of every human being and allowing a greater number of people to live in a given area.

Engineering allows us to produce lower temperatures in hot climates and higher temperatures in cold areas. Wireless telegraphy enables us to spread instruction and news around the globe. Thus we have increased the area which is inhabitable by man, improved and equalized the conditions under which the earth can be inhabited, and increased the possible number of people which can inhabit a given area. Think of the triumph of cotton planting in Egypt, of the Panama Canal, of the irrigation schemes in India and Iraq, of the reclaiming of the Zuider Zee in Holland.

(4) *Electrical engineering increases the physical and mental power and efficiency of each individual.* Let us first deal with the material side. The mastery of available materials and energies leads to a huge increase in production and a consequent cheapening of raw materials and finished products like food, clothing, dwellings, tools and also luxuries. The immediate consequence of the cheapening of these commodities is a vast increase in the individual comfort of those living in centres of production. It is not realized to what a tremendous extent engineering, and engineering alone, is responsible for this higher standard of living.

The next result made possible by transport was the spreading of these advantages and the equalizing of living conditions and comfort from town to country, from one climate to another, and from countries with old civilization to uncivilized territories.

(5) What of the mental side? Each new item of knowledge gained in the world is a step in the path of progress of mankind. Only by understanding can we create; only by creation can we progress. Consider the knowledge of matter and energy as it was only 200 years ago, and compare it with conditions to-day. I believe it was H. G. Wells who said recently: " If the time of human existence on this globe were represented by the span of a man's life, then it is only a day ago that we knew of steam and an hour ago that we knew of electricity." What has been achieved in these 60 minutes for mankind, as against the thousands of years that went before? How different is our conception of the world, of the elements and their composition, and of energy and its working. Think how only the fundamental laws, the law of conservation of mass, the law of conservation of energy and the law of dissipation of free energy, help us to understand our surroundings and all the problems connected with life. Without a knowledge of natural science and its applications, in which is bound up practically all the activity and the organization of modern society, an efficient grasp of the problems of the world, of life and of society seems impossible.

Our profession has just reached a stage at which it is impossible to keep our knowledge as that of a caste. It is essential that its fundamentals should and must become matters of general knowledge. In previous ages the knowledge of carrying arms, of handicraft, ethics, reading and writing, all originally known only to a few, had to be spread broadcast when it became evident that it mattered more than anything else in life and progress.

And now, finally, with the progress of the individual is bound up the progress of mankind. We have just seen that engineering has acted as perhaps the greatest democratizing agent. It has taught us to make full use of the materials and energies available, and thus, on the one hand by cheap production, and on the other by cheap transportation, has changed commodities and tools which were the properties of a few into the properties and tools of the masses of mankind.

Its next effect was to an ever-increasing extent to replace manual labour by other available energies, thus conferring a further boon on mankind by allowing us to spend our energy more and more in a form which we are allowed to call a higher one, that is, as mental energy.

The very great progress made in science during the last century is largely due to this fact. Through this emancipation of mental energy, science and knowledge, instead of being the labour of the few, have become the labour of many.

In conclusion, let us refer to a third factor which contributes to the efficiency of the human race. This efficiency, as has already been pointed out, greatly depends on the universal spreading of the knowledge or experience that has been gained by individuals either in theory or in practice. Such knowledge was originally part and parcel of the individual until language enabled him to communicate with his fellow men, and the written, and later the printed, sign allowed him to pass it on to a greater and greater number. To-day, the knowledge of one individual can, within an hour, become the knowledge of mankind in all distant parts of the globe. The transmission of messages by electric conduction or radiation has removed the time factor and the factor of distance from the spread of knowledge throughout civilization.

The picture is not complete, but I think I have shown that electrical engineering has led to a better understanding, to a more extended and efficient use of nearly all existing forms of matter and energy. It has led to a better understanding of animal and human organisms and problems. It has bridged space and time and minimized their influence where they had become resistance factors against energies mental and physical; it has increased the efficiency of individuals and of society and it has therefore proved to be perhaps the most important factor in the progress of mankind.

At present, either you are engaged in learning how to use the tools of your profession, or you have begun to apply them. You will go out into the world to build roads and bridges, to make or use internal-combustion engines or steam turbines, to spread electric power networks or erect wireless stations, to try to manufacture better or cheaper classes of products; and you will very often find that, whatever your particular work may be, it is sometimes tedious and uninteresting routine work, unsatisfactory and soul-depressing. There is only one thing which will help you to carry on and get through your work, and that is the knowledge that your life does not merely mean slaving for food, but that its inner meaning is team-work by which humanity shall be led out of its bondage to a better existence.

I have tried to show you the ideals underlying our profession. No man is happy if his work has only a relation to his own well-being. Happiness in life can only be found if we see a larger meaning in our work, a creation of values for a larger community. I have tried to show that our profession, in the creation of knowledge and in the application of such knowledge, has created modern society. It is your duty to use the tools which the pioneers have produced, and on your application of them in your life's work depends largely the future rate of progress of our country and mankind.

PROCEEDINGS OF THE INSTITUTION.

791st ORDINARY MEETING, 7th NOVEMBER, 1929.

Colonel Sir T. F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting held on the 24th October, 1929, were taken as read and were confirmed and signed.

Messrs. R. L. Bell and L. Champney were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows:—

ELECTIONS.

Associate Members.

Abbott, William St. George, Lieut.-Commdr. R.N.
Bennett, Abraham Francis.
Edgar, Edward James.
George, Henry Hale, B.E.
Hampson, William Wills.
Handy, William, M.B.E.
Jonas, Edward, D.Eng.
Lewis, Charles George H.
Mitchell, Gordon William B., B.A.
Moody, Harold Sydney, B.Sc.(Eng.).
Sowman, Alan Victor.
Swift, Leslie Albert.
Turner, Leonard George H.
Whipp, Fred.

Companions.

Barlow, The Rt. Hon. Sir C. A. Montague, Bart., P.C., K.B.E., M.A., LL.D.
Rubin, Albert Reginald.

Graduates.

Marwick, Robert William.
Nanda, Vasheshar Nath.
Owen, Albert Sydney H.A.
Phillips, William Eric, B.Sc.
Pitcher, Christopher Walter.
Pulling, Martin John L., B.A.
Smith, Charles Janson, Lieut. R.N.
Young, Tyrrell Francis, B.A.

Students.

Angold, George Henry C.
Ashthana, Rajendra Prasada, M.Sc.
Barnes, David Errington, B.Sc.
Barrett, Alfred Archibald.
Barton, Richard James.
Beresford, George.
Bhattacherjee, Barada Nath, B.Sc.
Bloor, Reginald Morris.
Bogra, Amir Chand.
Bradshaw, Harry Edward.
Brown, Edgar Louis.
Brown, Ian Harvey.
Chatterjee, Kamal Chandra.
Clarke, George Hessell K.
Din, Umar.
Edwards, John Griffiths.
Edwards, Noel Houghton.
Fenwick, William.
Fisher, Frank James.
Fox, John Ffoulkes.
Galley, Gordon William.
Gash, John Edward.
Gibson, Maurice.
Girdlestone, Richard Owen.
Greaves, John Milne.
Green, Robert.
Grote, Edwin Whitcomb.
Hargreaves, George.
Heyes, Vincent Gerrard.
Hobson, Frank.
Holmes, Victor Irving.
Horner, Frederick William L.
Hurdley, Thomas Charles.

Students—continued.

Hyde, Gilbert Anthony M., B.A.
Jones, Eric Owen.
Kashyap, Ram Nath.
Khandhar, Jagmohandas Popatlal.
Lyon, William Joseph R.
May, Henry John.
Nicoll, Robert Scott.
Owen, Edward Lionel.
Pett, John Percival C.
Radhakrishnan, Venkataramayer.
Ralphs, Leonard Charles.
Rishi, B. R.
Russell, Eric Ellis.
Sackville-Scott, Philip.
Saxen, Jerome Jaxon.
Setterfield, Edgar John.
Shivram, Tiruvottiyur Munuswami.
Singh, Gur Baksh.
Smith, Ernest Gilbert.
Smith, Ralph Balmforth.
Stanton, Thomas Leonard.
Stoyle, William Arthur R., B.Sc.
Stretton, Jack Arthur.
Swift, George.
Teal, Arthur Edward.
Thistleton, Richard.
Thomas, Howell Hugh.
Tudhope, Graham Wainwright.
Unne, Frank Ernest.
Wadhwa, Hans Raj.
Walker, Harold William.
Wilding, John Robert Harry.
Wilson-Dickson, William Gordon.
Wood, Thomas Lunn.
Yardley, Robert Oliver.

TRANSFERS.

Associate Member to Member.

Darling, Henry John.
Inglis, William.
Lawson, Robert Johnston.
Martinez, Giuseppe.
Radbone, Victor James.

Associate to Associate Member.

Bellhouse, Charles.

Graduate to Associate Member.

Agate, Purushottam Narayan, B.Sc.
Bullock, Percy Charles.
Clinton, James Stanley.
Davis, Basil Montefiore J.
Elliott, Harold John.
Emery, Arthur Joseph, B.Sc.(Eng.).
Frost, Albert Harry.
Garbutt, Sidney.
Geis, John Edward.
Ginno, Sidney Charles.
Gripper, Laurence Albert.
Harber, Frank Ollerenshaw.
Hodge, Gilbert Woffinton.
Hollin, Archibald Stewart.
King, Wallis Lovell.
McCollum, George.
Philpott, Stuart Fred.
Powell, Robert Desmond F.
Staygle, Edmund George.
Taylor, Edward Abraham.
Taylor, John Lishman.
Valentine, Arnot Stirling.

Student to Associate Member.

Macnee, Douglas Hamilton, B.Sc.

The President announced that, during the month of October, 42 donations and subscriptions to the Benevolent

Fund had been received, amounting in the aggregate to £103. A vote of thanks was accorded to the donors.

The President: To-night we have to thank two members for the notable additions which they propose to make to the Institution's collection of portraits in this Lecture Theatre. I shall first call upon Sir Thomas Callender to say a few words in regard to the portrait of Hopkinson.

Sir Thomas Callender: When I heard a short time ago that there were spaces on the Lecture Theatre walls which ought to be filled and that one of the portraits desired was that of my old friend John Hopkinson, I felt it incumbent on me to offer to provide it. I knew John Hopkinson for many years, both privately and in business, and I regard him as one of the great instances of a man of science being at the same time an exceedingly genial, happy and pleasant man with whom to deal. Among other pursuits he was particularly interested in mountaineering, and I have a vivid recollection of his recounting to me an adventure which he had had when mountaineering in the West of Scotland, where he missed disaster by only a few inches. I shall not endeavour to give a history of Hopkinson's achievements. The records of the Royal Society, of which he was for many years a Fellow, contain numerous descriptions of patents, lectures, and papers bearing his name and in all cases adding to his reputation. The same remark applies to the records of this Institution. As we all know, Hopkinson was a Lancashire man; he came from Manchester. Like all Manchester men, and especially those born about the same year as himself, in 1849, he was interested in engineering and music. In his early youth it was suggested that he should join his father in business, but, fortunately, those who were responsible for his education decided that he should go to Cambridge. He possessed a wonderful mind and great powers of application; he became a Double Wrangler (the first, I believe, to achieve that distinction) and won other honours, and by the time he left Cambridge he was an outstanding figure in electrical science and in engineering. Hopkinson began his practical life work in connection with lighthouse engineering, and he was responsible for important improvements therein. Later, when he devoted his life work to electrical engineering, he did more than anyone to give us the means of distributing electrical energy as light or power. He was, indeed, responsible for many vital improvements in the production of this form of energy. The subject of light provided his occupation throughout his life. We say that a man who makes two blades of grass grow where one grew before is worthy of honour; and so, also, the man who makes it possible to distribute electricity over three or four times the distance that was possible before his advent is worthy of honour: and that is only one of the things for which honour is due to Hopkinson. It has always been a source of the greatest happiness to me that I was with him at the very beginning of his work. I had some difficulty in getting an artist to undertake the task of painting this portrait; but I think that we have succeeded, as both the artist and myself have been helped by many members of this audience; and Mrs. Hopkinson herself has done immense service in that way. To her, to all those who helped me to collect the necessary data, and also to the artist, Mr. R. H. Campbell, I desire to express my thanks. I now ask the President to accept the picture for the Institution as a humble tribute to my knowledge of John Hopkinson as a very lovable man, an exceedingly great scientist, and one who did much for electrical engineering in all its branches.

Mr. W. M. Mordey: I am one of those who knew John Hopkinson fairly well, and all that has been said about his work and character I entirely endorse. He was undoubtedly a great man. With regard to the portrait, the artist, Mr. R. H. Campbell, did not know Hopkinson, but his talent and industry enabled him to make the admirable and lifelike portrait for which we now have to thank Sir Thomas Callender. Twenty years ago my last task on stepping down from the presidential chair was to receive from Mrs. Hopkinson the marble bust of John Hopkinson by Sir Hamo Thornycroft which now adorns this building. It was presented to us by Bertram Hopkinson on behalf of his mother, who was present and whom we are very glad to welcome here to-night. Bertram Hopkinson in many respects shared the gifts of his father; and on that occasion he gave a short but excellent sketch of his father's life and work. I should like to call the attention of the members, and particularly the younger members, to that sketch of his father which they will find in the *Journal.** I suggest that they should also read the memoir which Bertram Hopkinson wrote as a preface to the two volumes of his father's collected works, which were published in 1901. These two volumes contain 58 papers or addresses, all of a very high standard, and include the addresses given by Hopkinson when he was twice our President. As illustrating the value of his work I may perhaps be allowed to refer in particular to two of those papers. In 1884, Silvanus Thompson published the first edition of his book on "The Dynamo." At the end of the preface he wrote: "We want some new philosopher to do for the magnetic circuit what Dr. Ohm did for the voltaic circuit 50 years ago. Until we know the true law of the electromagnet there can be no true or complete theory of the dynamo." The "new philosopher" was John Hopkinson. I do not know to what extent, if at all, Hopkinson was led to undertake his investigations by those words of Silvanus Thompson, but the following year he read his great paper † on "The Magnetization of Iron" before the Royal Society, giving us the true law of the electromagnet; and in 1886, in another paper before the Royal Society, he and his brother Edward gave us the true law of the dynamo.‡ By those two papers the knowledge of the dynamo was raised from chaos to an orderly science. I have now formally to ask you to thank Sir Thomas Callender for the beautiful portrait which he has given us, to assure him that we accept it with gratitude and that it shall occupy a place of honour in the company of our portraits of Faraday, Kelvin, Volta and Wheatstone.

The President then called upon Mr. Ll. B. Atkinson to say a few words with regard to the portrait of Maxwell.

---

* *Journal I.E.E.*, 1910, vol. 44, p. 2.

† *Proceedings of the Royal Society*, 1885, vol. 38, p. 265.

‡ "Dynamo-Electric Machinery": *Philosophical Transactions of the Royal Society*, 1886, vol. 177, p. 359.

Mr. Ll. B. Atkinson: When, three years ago, the Council decided to endeavour to decorate the Lecture Theatre with portraits of the pioneers of electrical science, the benefits of whose work are reaped by us all, I asked that I might be allowed to contribute a portrait of James Clerk Maxwell. The selection of material for a posthumous portrait is always a difficult task. There were in existence certain photographs of Clerk Maxwell, taken at various ages. Most of them were in the library at Trinity College, Cambridge, where I and the artist, Mr. R. H. Campbell, visited them and looked them over. There are two others that are of importance. Of one of them we have a copy hanging in the Common Room in this building. The other, which was selected as the more pleasing, was a side-view photograph, and the copy of it from which we worked was very kindly given to me by Sir Ambrose Fleming, who, by the great interest he has taken and the visits he has made to the studio during the progress of the work, has done much to help to produce this very successful portrait. I should like, in addition, to thank Sir Arthur Schuster, who visited the studio and helped the artist in matters of colouring and the like. Both these gentlemen knew Maxwell personally. As it is 50 years since his death, there are not many now living who really knew him during his lifetime. The object shown on the table at the side of the picture is the revolving-coil apparatus which was designed by Lord Kelvin, and with which, in 1863, at King's College, London, the first determination of the value of the ohm in electromagnetic units was made, by Maxwell himself, working with Balfour Stewart and Fleeming Jenkin. Next let me express my grateful acknowledgments to the artist, Mr. R. H. Campbell, who has, I think, made a very beautiful representation from a scanty foundation. In 1881 I was a student at evening classes under the late Professor Ayrton, and I remember that one night he referred us to Maxwell's treatise on electricity. Shortly afterwards this book came into my possession. Much of the mathematics in it is beyond my scope, but I have read it again and again, and I dare say I shall read it many more times. It was published in 1873, and had been 10 years or more in the making, for much that was fundamental in it was contained in the paper which Maxwell presented in 1864 to the Royal Society on the dynamical theory of the electromagnetic field. This is not the place to detail the profound change in thought regarding electricity and magnetism and their actions that was brought about by that paper and by his subsequent treatise. Maxwell laid down, in equations and verbally, the conditions governing the properties of the electromagnetic field in a relatively stationary medium or ether, and the principle that changes of state produced at one point in such a field were propagated like a wave to other points. Notwithstanding the immense changes in our knowledge of physics and electricity since that date, his equations, modified to cover moving media, are by common agreement accepted to-day. Of his work in colour vision, thermodynamics, the theory of gases and the viscosity of gases, only mention can be made, but in all of them his work was fundamental. As to Maxwell—the man—I quote from the " Life of Maxwell " by Lewis Campbell and William Garnett: " The leading note of Maxwell's character is a grand simplicity, and in attempting to analyse it we find a complex of qualities that exist separately in other and smaller men. Extraordinary gentleness is combined with keen penetration, wonderful activity with no less wonderful repose, personal humility and modesty with intellectual scorn. His deep reserve in common intercourse was commensurate with the fulness of his kindly outpourings for those he loved. Not less instinctive was the sense of equality in all human beings which underlay the plainness of his address, but, on the other hand, his respect for the actual order of the world and for the wisdom of the past was at least as steadfast as his faith in progress. While fearless in speculation, he was strongly conservative in practice. In his intellectual faculties there was also a balance of powers which are often opposed. His imagination was in the highest sense concrete, grasping the actual reality and not only the relation of things. No one was ever more impatient of mere abstractions. Once more, while he was continually striving to reduce to greater definiteness man's conceptions of physical laws, he seemed habitually to live in a sort of mystical communion with the infinite." I have much pleasure in asking the Institution to accept this portrait.

Sir Ambrose Fleming: By the kindness of the President I am permitted to accept, on behalf of all the members of the Institution, this portrait of James Clerk Maxwell donated to us by Mr. Atkinson. It is noteworthy that this presentation is made just two days over 50 years from the death of Maxwell at Cambridge, on the 5th November, 1879. When we remember all the immense achievements which have taken place since that date in the utilization of those electromagnetic waves which Maxwell was the first to recognize and discuss, I am sure we all feel that it was an absolute necessity for the Institution to possess some worthy representation of this great pioneer. I am probably one of very few present who knew Maxwell personally. I attended his lectures and worked under him in the Cavendish Laboratory in the last few years of his life, and I can testify to the excellence of this portrait as a likeness of Maxwell at his best. Maxwell's work was far too extensive to be referred to, even in the faintest outline, in a single speech, but I trust that it may be possible to have Maxwell Lectures established, analogous to the Kelvin Lectures which are given annually, to commemorate that great work. Maxwell was an extraordinary man, and an inspiration to all who came in contact with him. During one of the last lectures he gave at Cambridge, an American sitting next to me turned to me and said, " Sir, this man is great. He does not come here and tell us what he has read in books; he gives it to us hot from his brain." That is what he always did. I therefore, on behalf of all the members, gratefully accept this portrait from Mr. Atkinson, and assure him it will always be esteemed by us as a valuable memorial of one who was not only a great scientific investigator, but a truly great man.

The President: We accept these beautiful gifts from Sir Thomas Callender and Mr. Atkinson with the highest appreciation and the most hearty thanks; and in saying so I know that I am speaking for every individual member of this Institution.

A paper by Messrs. B. A. G. Churcher, Member, and A. J. King, Associate Member, entitled "The Analysis and Measurement of the Noise emitted by Machinery" (see page 97), was then read and discussed.

On the motion of the President a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 8.15 p.m.

INSTITUTION NOTES.

Summer Meeting.

By invitation of the Committee of the Irish Centre the next Summer Meeting of the Institution will be held in Ireland from the 2nd to the 6th June, 1930. Full particulars will be circulated in due course.

National Certificates and Diplomas in Electrical Engineering (England and Wales).

The undermentioned colleges have been approved under the scheme drawn up by the Board of Education and the Institution:—

Approved for Ordinary Grade Certificates (Senior Part-time Course).

Southampton University College.

Approved for Higher Grade Certificates (Advanced Part-time Course).

Crewe Technical Institute.
Sheerness Technical Institute.
Walsall Technical College.

Prizes for Papers by Students, and Graduates up to the Age of 28.

The Council have accepted an offer from a member of the Institution to present this session a Prize (value £10), and a further Prize of a like amount next session, for the best paper submitted by a Student, or a Graduate up to the age of twenty-eight, on the subject of "The Relations between Economics and Engineering."

Papers submitted for the present session's Prize must reach the Secretary not later than the 1st May, 1930. All papers submitted must have been specially written for the purpose and must not have previously been read or published elsewhere.

It should be particularly noted that only Students of the Institution and those Graduates under 28 years of age on the 1st January, 1930, are eligible to compete.

The Council reserve the right to postpone the award and, if necessary, to open a fresh competition in the event of none of the papers submitted being sufficiently meritorious.

The Benevolent Fund.

An appeal to members to support the Fund will be found on the last page of the cover of this issue of the *Journal.*

Lead-Sheathed Cables.

By the decision of the Council the following letter has been sent to the technical Press:—

THE INSTITUTION OF ELECTRICAL ENGINEERS,
SAVOY PLACE, W.C. 2.
9th December, 1929.

DEAR SIR,

SMETHWICK FIRE DISASTER.

The attention of the Council of the Institution of Electrical Engineers has been drawn to newspaper reports of the proceedings at the inquest, which concluded on the 25th September last, upon eleven persons who lost their lives by reason of a fire at premises in Rolfe Street, Smethwick, on the 2nd September.

Some of the evidence purported to show that the fire was due to a defective electrical installation in a neighbouring building, and in this connection one of the witnesses condemned the use of lead-covered rubber-insulated cables for the wiring of public buildings. This statement has caused great uneasiness in the minds of consulting engineers, architects, electrical contractors and others, inasmuch as the use of lead-covered rubber-insulated cables is permitted by, and the proper methods of installation of such cables are set out in, the "Regulations for the Electrical Equipment of Buildings" issued by the Institution. These Regulations are recognized by consulting engineers, electrical contractors, electricity supply authorities and the Fire Offices, as representing the best standard practice, and the Fire Offices in particular recommend their use.

The Council re-affirm, therefore, that they are of the opinion that lead-sheathed cables are both suitable and safe for electrical installations if installed and maintained in accordance with the I.E.E. Wiring Regulations.

From the evidence given, as reported in the newspapers, there is every indication that the electrical installation which, it is suggested, caused the fire at Smethwick, did not comply with these Regulations.

I am, dear Sir, yours faithfully,
P. F. ROWELL,
Secretary.

Proceedings of the Wireless Section.

78th Meeting of the Wireless Section,
6th November, 1929.

Colonel Sir T. F. Purves, O.B.E., President, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 1st May, 1929, were taken as read and were confirmed and signed.

A vote of thanks to Commander J. A. Slee for his services as Chairman of the Wireless Section during the session 1928–29, proposed by Lieut.-Col. A. G. Lee, O.B.E., M.C., B.Sc., and seconded by Major B. Binyon, O.B.E., M.A., was carried with acclamation.

Captain C. E. Kennedy-Purvis, R.N., Chairman of the Wireless Section, then delivered his Address (see page 16).

A vote of thanks to Captain Kennedy-Purvis for his Address was proposed by the President and, after being put to the meeting, was carried with acclamation.

The meeting terminated at 7 p.m.

79th Meeting of the Wireless Section,
4th December, 1929.

Captain C. E. Kennedy-Purvis, R.N., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 6th November, 1929, were taken as read and were confirmed and signed.

A paper by Mr. G. Shearing, B.Sc., and Captain J. W. S. Dorling, R.N., Members, entitled "Naval Wireless Telegraph Communications," was read and discussed.

The meeting terminated at 7.55 p.m. with a vote of thanks to the authors, which was moved by the Chairman and carried with acclamation.

Proceedings of the Meter and Instrument Section.

6th Meeting of the Meter and Instrument Section,
1st November, 1929.

Colonel Sir T. F. Purves, O.B.E., President, took the chair at 7 p.m.

The minutes of the meeting of the Section held on the 5th April, 1929, were taken as read and were confirmed and signed.

The President, after announcing the constitution of the Committee for 1929–1930 (see page 84), then vacated the chair, which was taken by Mr. E. W. Hill, Chairman of the Section, who delivered an Address (see page 24).

A vote of thanks to Mr. E. W. Hill for his Address was proposed by the President and, after being put to the meeting, was carried with acclamation.

The meeting terminated at 8.45 p.m.

7th Meeting of the Meter and Instrument Section,
6th December, 1929.

Mr. E. W. Hill, Chairman of the Section, took the chair at 7 p.m.

The minutes of the meeting of the Section held on the 1st November, 1929, were taken as read and were confirmed and signed.

A paper by Dr. C. V. Drysdale, O.B.E., F.R.S.E., Member, entitled "Alternating-Current Potentiometers and their Applications," was read and discussed.

On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 8.55 p.m.

International Illumination Congress, 1931.

An International Illumination Congress, under the auspices of the International Commission on Illumination, will take place in Great Britain during the period 3rd to 13th September, 1931.

Visits will be made to places of interest in England and Scotland and papers dealing with the most varied aspects of lighting will be presented. These will be grouped so as to ensure, as far as possible, that all interests are fully covered at each local centre. The Congress will be followed by the technical meetings of the International Commission on Illumination, which will be held in Cambridge from September 13th to 19th, 1931.

Several committees are already at work on the arrangements, fuller particulars of which will be announced in due course.

The Honorary General Secretary of the Congress is Colonel C. H. Silvester Evans (c/o The Illuminating Engineering Society, 32, Victoria Street, London, S.W.1), to whom all communications should be addressed.

Representatives of the Institution on Other Bodies.

The following is a list of representatives of the Institution on other bodies, and the dates on which they were appointed:—

Bristol University:
Mr. H. F. Proctor (8 Jan., 1925).

British Cast Iron Research Association:
Mr. E. B. Wedmore (25 Sept., 1924).

British Electrical and Allied Industries Research Association:
Capt. J. M. Donaldson, M.C. (8 Nov., 1928).
Mr. P. V. Hunter, C.B.E. (19 Dec., 1929).
Mr. R. W. Paul (21 Jan., 1926).
Dr. A. H. Railing (19 Dec., 1929).
Mr. C. P. Sparks, C.B.E. (20 Nov., 1924).

Sectional Committee on Electric Control Apparatus Research:—
Major H. C. Gunton (2 Feb., 1921).
Mr. W. E. Highfield (19 Mar., 1925).

Sub-Committee on Connections to Large Gas-filled Lamps:—
Mr. C. C. Paterson, O.B.E. (24 Oct., 1929)
Mr. B. Welbourn (24 Oct., 1929).

British Electrical Development Association:
Capt. J. M. Donaldson, M.C. (4 Feb., 1926).
Mr. C. C. Paterson, O.B.E. (14 Feb., 1929).
Mr. H. T. Young (16 Feb., 1928).

Advisory Exhibition Committee:
Mr. Ll. B. Atkinson (30 Sept., 1926).

Electric Vehicle Committee :
Col. R. E. Crompton, C.B. (22 Oct., 1925).
Mr. W. R. Rawlings (22 Oct., 1925).

Sub-Committee on Constitution:
Capt. J. M. Donaldson, M.C. (4 Dec., 1925).

Sub-Committee on Rural Electrical Development :
Capt. J. M. Donaldson, M.C. (20 Oct., 1927).
Mr. R. Grierson (20 Oct., 1927).

British Engineering Standards Association :

Council :
Mr. Ll. B. Atkinson (21 Jan., 1926).
Col. R. E. Crompton, C.B. (21 Jan., 1926).
Mr. C. P. Sparks, C.B.E. (21 Jan., 1926).

Electrical Industry Committee :
Dr. W. H. Eccles, F.R.S. (17 Feb., 1927).
Lt.-Col. K. Edgcumbe, T.D., R.E.T. (Ret.) (5 Mar., 1925).
Mr. F. Gill, O.B.E. (21 May, 1914).
Mr. J. S. Highfield (21 May, 1914).
Mr. R. T. Smith (21 May, 1914).
Mr. W. B. Woodhouse (19 Dec., 1918).

Technical Committee on Electricity Meters :
Mr. C. H. W. Gerhardi (7 Nov., 1929).
Mr. S. W. Melsom (21 Jan., 1926).
Mr. G. F. Shotter (28 Feb., 1929).

Technical Committee on Electrical Accessories :
Mr. H. J. Cash (31 Mar., 1925).
Mr. F. W. Purse (31 Mar., 1925).

Technical Committee on Electrical Instruments :
Lt.-Col. K. Edgcumbe, T.D., R.E.T. (Ret.) (15 Feb., 1923).

Technical Committee on Electrical Nomenclature and Symbols :
Mr. C. C. Paterson, O.B.E. (8 Jan., 1920).

Technical Committee on Nomenclature :
Mr. A. T. Dover (21 Nov., 1929).

Technical Committee on Overhead Transmission Lines Material :
Mr. P. Rosling (5 Mar., 1925).

Technical Committee on Standardization of Wireless Apparatus and Components :
Mr. E. H. Shaughnessy, O.B.E. (30 Sept., 1925).

Sub-Committee on Conduit Fittings :
Mr. H. J. Cash (18 May, 1927).

Sub-Committee on Distribution Boards :
Mr. E. B. Hunter (25 Feb., 1927).
Mr. S. W. Melsom (25 Feb., 1927).

Sub-Committee on Low-Voltage Cut-outs :
Mr. H. J. Cash (22 June, 1926).
Mr. E. B. Hunter (25 Feb., 1927).
Mr. S. W. Melsom (25 Feb., 1927).

Sub-Committee on Mains Supply Units :
Mr. R. Grierson (31 Oct., 1928).
Mr. F. W. Purse (16 Oct., 1928).

Sub-Committee on Prime Movers for Electrical Plant :
Mr. J. Rosen (20 Oct., 1927).

Sub-Committees on Switches, Ceiling Roses, Wall-plug Sockets and Connectors for Portable Apparatus :
Mr. H. J. Cash (23 Jan., 1924).
Mr. F. W. Purse (23 Jan., 1924).

Sub-Panel on Graphical Symbols for Interior Installations :
Mr. J. R. Cowie (13 Nov., 1924).

Illumination Industry Committee :
Lt.-Col. K. Edgcumbe, T.D., R.E.T. (Ret.) (28 Feb., 1924).
Mr. P. Good (28 Feb., 1924).
Mr. H. T. Harrison (28 Feb., 1924).
Prof. J. T. MacGregor-Morris (28 Feb., 1924).
Mr. J. M. G. Trezise (19 Mar., 1925).

Technical Committee on British Standards in Colonial and Foreign Trade :
The President (*ex-officio*).

Technical Committee on Coal :
Mr. W. M. Selvey (19 Jan., 1928).

Technical Committee on Colliery Requisites :
Mr. C. T. Allan (3 July, 1924).

Glasgow Regional Committee :
Mr. F. Anslow.

Manchester Regional Committee .
Mr. W. T. Anderson.

Newcastle Regional Committee :
Mr. S. A. Simon.

Sheffield Regional Committee :
Mr. M. Wadeson.

Technical Committee on Petroleum Products :
Mr. H. W. Clothier (1 Feb., 1923).

Technical Committee on Pipe Flanges :
Mr. W. M. Selvey (14 April, 1921).

Technical Committee on Railway Signalling Apparatus :
Mr. A. F. Bound (24 Oct., 1929).

Technical Committee on Rating of Rivers :
Mr. G. K. Paton (20 Oct., 1927).

Sub-Committee on Mining Electrical Plant :
Mr. C. P. Sparks, C.B.E. (23 April, 1925).

Sub-Committee on Portable Railway Track :
Mr. R. T. Smith (25 Oct., 1928).

Sub-Committee on Rubber Belting :
Mr. C. Rodgers, O.B.E., B.Sc., B.Eng. (5 Jan., 1928).

Sub-Committee on Tubular Tramway Poles :
Mr. T. L. Horn (4 Feb., 1926).

City and Guilds of London Institute, Fellowship Committee:
Dr. W. H. Eccles, F.R.S. (19 April, 1928).

Council for the Preservation of Rural England:
Mr. J. M. Kennedy (10 Jan., 1929).

Engineering Joint Council:
Col. Sir T. F. Purves, O.B.E. (24 Oct., 1929).
Sir Archibald Page (2 Feb., 1928).

Imperial College of Science and Technology, Governing Body:
Mr. W. M. Mordey (12 April, 1923).

Imperial Minerals Resources Bureau Conference, Copper Committee:
Mr. B. Welbourn (18 Sept., 1919).

Institute of Metals, Corrosion Research Committee:
Mr. W. M. Selvey, (19 July, 1923).

Institution of Civil Engineers, Engine and Boiler Testing Committee:
Mr. R. A. Chattock (19 Oct., 1922).
Mr. C. P. Sparks, C.B.E. (19 Oct., 1922).

International Association for Testing Materials:
Mr. J. M. Kennedy (5 July, 1928).

International Illumination Commission, British National Illumination Committee:
Lt.-Col. K. Edgcumbe, T.D., R.E.T. (Ret.) (27 Nov., 1913).
Mr. P. Good (18 Sept., 1919).
Mr. H. T. Harrison (27 Nov., 1913).
Prof. J. T. MacGregor-Morris (27 Nov., 1913).
Mr. J. M. G. Trezise (19 Mar., 1925).

International Scientific Unions:
Committee on International Union in Physics:
Dr. A. Russell, F.R.S. (18 Mar., 1920).

Committee on International Union in Radio-Telegraphy:
Dr. W. H. Eccles, F.R.S. (18 Mar., 1920).
Prof. G. W. O. Howe, D.Sc. (18 Mar., 1920).
Prof. E. W. Marchant, D.Sc. (18 Mar., 1920).

Leeds Municipal Technical Library Committee:
Mr. W. B. Woodhouse (19 Dec., 1918).

Loughborough Technical College, Advisory Committee:
Mr. Ll. B. Atkinson (11 April, 1929).

Metalliferous Mining (Cornwall) School, Governing Body:
Mr. L. A. Hards (1 Dec., 1927).

Middlesbrough Technical College, Governing Body:
Mr. E. Edwards (1 Oct., 1925).
Mr. J. M. Gibson (1 Oct., 1925).

National Certificates and Diplomas in Electrical Engineering, Joint Committee (England):
Mr. W. E. Highfield (5 Jan., 1928).
Prof. E. W. Marchant, D.Sc. (5 Jan., 1928).
Mr. W. M. Selvey (5 Jan., 1926).

National Physical Laboratory, General Board:
Dr. W. H. Eccles, F.R.S. (21 Oct., 1926).
Dr. A. Russell, F.R.S. (22 Nov., 1923).

National Register of Electrical Contractors:
Col. R. E. Crompton, C.B. (18 Feb., 1926).
Mr. P. V. Hunter, C.B.E. (18 Feb., 1926).
Mr. W. R. Rawlings (18 Feb., 1926).
Mr. W. M. Selvey (18 Feb., 1927).

Professional Classes Aid Council:
Mr. P. F. Rowell (20 April, 1928).

Radio Manufacturers' Association, Committee on Battery Eliminators:
Mr. J. R. Dick, B.Sc. (3 April, 1928).

Royal Engineer Board:
Mr. W. B. Woodhouse (19 Mar., 1925).

Royal Society:
Alloys of Iron Research Committee:
Mr. J. Swinburne, F.R.S. (15 Feb., 1923).

National Committee on Physics:
Dr. A. Russell, F.R.S. (16 Dec., 1920).

National Committee on Radio-Telegraphy:
Col. A. S. Angwin, D.S.O., M.C. (7 April, 1927).
Prof. C. L. Fortescue, O.B.E., M.A. (20 Oct., 1927).

Smoke Abatement League of Great Britain:
Mr. H. C. Lamb (8 April, 1926).
Mr. S. J. Watson (8 April, 1926).

Union of Lancashire and Cheshire Institutes (Panel for Engineering):
Mr. A. P. M. Fleming, C.B.E., M.Sc. (28 Feb., 1924).
Prof. Miles Walker, D.Sc. (28 Feb., 1924).

War Office Mechanical Warfare Board:
Dr. W. H. Eccles, F.R.S. (19 Jan., 1928).

Women's Electrical Association:
Mr. A. P. M. Fleming, C.B.E., M.Sc. (18 Dec., 1924).

Women's Engineering Society:
Mr. A. P. M. Fleming, C.B.E., M.Sc. (25 Sept, 1924).

World Power Conference (British National Committee):
Mr. B. Welbourn (24 Oct., 1929).

LOW-TEMPERATURE CARBONIZATION OF FUEL, WITH SPECIAL REFERENCE TO ITS COMBINATION WITH THE PRODUCTION OF ELECTRICITY (AMERICAN PRACTICE).

By S. McEwen.

[*Paper received* 1*st October*, 1929; *read at a Joint Meeting of* The Institution *and the* Institute of Fuel 21*st November*, *and before the* Tees-Side Sub-Centre 4*th December*, 1929, *also before the* Mersey and North Wales (Liverpool) Centre 20*th January*, 1930.]

Summary.

In this paper consideration is given to the possibility that the pre-treatment of coal with recovery of by-products may secure an economic advantage in the production of electricity in the United States of America.

Reference is made to the trend of opinion in the minds of power station engineers and to the great interest which is maintained in the subject.

The economic possibilities are reviewed and stress is laid on the necessity for securing a maximum revenue from the sale of such gas as is produced by the process of pre-treatment, and it is claimed that this result can be obtained only by co-operation with public service companies supplying gas to domestic and industrial concerns.

The installation of the McEwen-Runge process at the Lakeside station of the Milwaukee Electric Railway and Light Co. is described and an account is given of its development so far as it has been continued in America, the earlier experimental work which originated in England being omitted. Particulars are given of the progress which has been made, together with an indication of the direction which future development will follow.

In America, the measure of interest in the pre-treatment of coal as a preliminary to combustion for the purpose of generating electric power is evidenced by the fact that the Prime Movers Committee have issued serial reports under the title "Distillation Products of Coal." A sub-committee was appointed to deal with this subject.

The first report was issued in July 1928, and announced that the interest of American engineers in the distillation products of coal is increasing. The report constitutes a review of the better-known processes, both of American and European origin, together with statements referring to the advance in theoretical knowledge of the subject. The general position was summed up in the following statement:—

"There have been no startling developments in any of the processes during the past year. Steady progress has been made in the commercialization of certain of these processes and these advances are being closely followed by interested engineers."

A year later, in June 1929, a further serial report was issued wherein the developments of the past year were reviewed. The following are extracts from that report:—

"From the purely commercial standpoint, for conditions in this country it appears that no process has as yet proved itself in practice, particularly for use in connection with steam power plants. It is, of course, such a development that most interests the engineer entrusted with the design of power plants in his search for the process making the highest economic use of fuel.

"Power plant engineers in this country centre their interest on the McEwen-Runge plant installed at Milwaukee."

In view of this statement by the Prime Movers Committee, no apology need be offered for dealing in this paper primarily with the McEwen-Runge process. Before proceeding to describe this process and giving an account of the progress which has been made in its development, it is desirable that the economic possibilities in connection with the pre-treatment of coal should be realized and the conditions which are essential for commercial success should be clearly understood. It is not merely sufficient to achieve a technical success, for a process which is both technically and commercially successful when applied to the pre-treatment of coal with domestic fuel as one of the products might not be commercially successful if the solid fuel were utilized for power production instead of for domestic purposes. Fuel for the latter purpose can be sold at a high price, generally very much higher per unit of weight than that of the coal from which it was produced, but the power station engineer of to-day is only concerned with heat units; he is not so much concerned with the physical condition in which the fuel is supplied to him. He has methods at his disposal which will enable him to convert an equally high percentage of those heat units into electrical energy whether the fuel is in the form of powder, grains or lumps. The pre-treatment of coal with a recovery of by-products, which is to be followed by the combustion of the solid residue, is not favoured by any appreciation in the value of the solid residue; the latter has to be sold to the power producer at a price per heat unit which is equivalent to the price of a heat unit in the raw coal. The revenue obtained from the sale of the liquid and gaseous by-products has to pay the whole cost of pre-treatment and, after an allowance for the loss of weight of the solid residue as compared with the original coal, provide an adequate profit to warrant the undertaking. It is for this reason that a low-temperature process operated in conjunction with a plant for electric power generation has a much smaller margin for profit than is the case with low-temperature processes which yield, as one of the main products, a high-grade domestic fuel. To secure an equivalent profit it is essential that the pre-treatment plant for use in conjunction with a power plant be cheaper to operate, have a lower capital cost and secure the maximum possible revenue from all of the by-products. These conditions involve the production of gas which can be sold for town supply, because conditions in America indicate that should the gas be burned under the boilers and the B.Th.U. in that gas be credited to the carbonization plant at a rate per B.Th.U. slightly above that of the original coal, the pre-treatment process would be handicapped to the point of economic failure. This conclusion points to the necessity for a working alliance between the electric power producer and the town gas distributor.

It may be said that it is not necessary to develop a low-temperature carbonization process in order to give effect to an alliance between electric power and town gas undertakings, and it is possibly doubtful whether so much interest would have been taken by power station engineers in low-temperature carbonization were it not for the fact that the coke produced by high-temperature processes is not favoured by power station engineers as a fuel. The justification for the development of low-temperature carbonization in this connection lies in the fact that semi-coke is an ideal fuel for combustion, while the net revenue from the by-products of a low-temperature process promises to be greater than that from the by-products of a high-temperature process.

Many investigations have been made from time to time for the purpose of determining whether the cost of generating a unit of electric power can be reduced by pre-treating coal, and perhaps one of the most interesting studies which has been made available through the technical Press is that embodied in the report which was made to the E. L. Phillips Co. of New York, a summary of which has been published* by W. R. Knapp and P. McMichael. Eight studies were made of different combinations to show the possibility of obtaining cheaper power by pre-treating coal. These studies cover combinations of a power station with standard coke-oven plants and with complete gasification plants, showing the cost of power when the various products are either consumed as fuel for power production or sold for public service. The study purports to include low-temperature carbonization as one of the possible combinations alternative to high-temperature carbonization, but the application of the low-temperature system is contrary to the best practice and, therefore, has little significance. The report, however, is of great value in showing the importance of securing a good revenue for the sale of gas to ensure a profitable combination of pre-treatment and power generation. Very definite information of costs, yields and revenue from high-temperature coke-oven plants was available to Messrs. Knapp and McMichael, this being an established industry, whereas no similar information regarding the low-temperature carbonization industry was available. The most profitable combination is shown in Table 1.

TABLE 1.

	Steam generated with	
	Pulverized low-grade coal	Pulverized coke and breeze (Total oven gas sold)
Capital investment:—	$	$
Power plant	17 073 000	17 073 000
Gas plant	—	5 607 000
Total	$17 073 000	$22 680 000
Cost per kWh produced:—	mills	mills
Operation: labour, maintenance and supplies ..	0·595	1·460
Interest and depletion ..	0·048	0·149
Fixed charges, 15 per cent	3·248	4·315
Coal	1·324	2·221
Total operation expense	5·215	8·145
Revenue from by-products	—	3·669
Net operation expense..	5·215	4·476
Change in cost of power ..	—	+ 0·739
Additional investment:—		$
Gross amount	—	5 607 000
Change in cost of power ..	—	+ 582 927
Return on additional investment	—	per cent 10·38

Table 1 shows that it is profitable to combine pre-treatment of coal with power generation, but the figures are based upon the assumption that high-temperature oven coke can be efficiently burned under the boilers in the power station, and it is also assumed that the coal to be carbonized in coke ovens would have to be of a higher grade and more costly than the low-grade coal suitable for direct firing under the boilers. Without referring more specifically to studies of the various combinations, it may be said that Table 1 clearly shows that there is either absence of profit or considerable loss unless the whole of the gas made is sold for town supply.

The important position which the revenue from the sale of gas occupies in the economics of pre-treatment may be realized if the revenue from by-products is analysed per ton of coal treated, which is possible with the aid of the data given in the published summary by Messrs. Knapp and McMichael.

TABLE 2.

Costs		Revenue	
	$		$
Coal	2·650	Coke and breeze	1·805
Operation, including labour, supplies, heating and maintenance ..	1·356	Tar	0·600
Capital and overhead charges ..	1·600	Gas	3·600
		Light oil ..	0·300
		Ammonium sulphate ..	0·375
Total costs ..	$5·606	Total revenue	$6·680

Net profit per ton of coal treated = $1·07.

---

* *Power*, 1929, vol. 69, p. 665.

The revenue from the sale of gas is seen to be $3·60 for each ton of coal treated, a figure in excess of the original cost of the coal per ton, and it is based upon a selling price for the gas of 30 cents per 1 000 cubic ft. of 530-B.Th.U. gas. If this gas were burned under the boilers it would have a value per B.Th.U. only slightly above that of 1 B.Th.U. in coal and the revenue would be reduced from $3·6 to $0·6, and the profit of $1·07 per ton would be converted into a loss of nearly $2 per ton.

Since it has been clearly established that in America a very high revenue can be secured by the disposal of gas for public service, it would follow that the ideal pre-treatment process would be one yielding the maximum quantity of saleable gas, unless it could be established that a reduction in the quantity of gas produced was accompanied by an improvement in the quality of other products with a proportionately greater revenue therefrom. If a yield of the maximum quantity of gas under high-temperature conditions results in the production of a solid residue of little value to the power station engineer, then the pre-treatment process must be varied to yield a residue which will be acceptable to him. It is also important to establish the relative value of gas and low-temperature tar, since one of the characteristics of a low-temperature system is a high yield of liquid by-products at the expense of gas. For a study of these relative values it is convenient to set out the realizable value of the various products in cents per 100 000 B.Th.U.

Dealing first with high-temperature carbonization, and using the figures reported by Messrs. Knapp and McMichael, we find the revenue per 100 000 B.Th.U. from each product to be as given in Table 3.

TABLE 3.

Product	Price and particulars	Revenue per 100 000 B.Th.U.
		cents
Coal ..	$2·65 per ton (13 900 B.Th.U. per lb.)	0·9
Coke ..	$2·37 per ton (13 170 B.Th.U. per lb.)	0·9
Tar ..	6 cents per gal. of 8 lb.	4·42
Gas ..	30 cents per 1 000 cub. ft. (530 B.Th.U. per cub. ft.)	5·66
Light oil..	10 cents per gal. of 6½ lb.	7·7

It is customarily claimed for a low-temperature process that the high yield of liquid by-products more than compensates for the low yield of gas, but, if this claim is to be justified, then the realizable value of the tar per 100 000 B.Th.U. must be sufficiently higher than that secured by high-temperature tar to make it equal to the value of gas and, in addition, to compensate for the volatile matter allowed to remain in the semi-coke which brings a low rate of revenue.

For tar to secure the same revenue as gas per 100 000 B.Th.U. it must realize at least 7·7 cents per American gallon, and a higher revenue than this must be obtained if compensation has to be made for the unextracted volatile matter.

It is not difficult to show that low-temperature tar can be made to realize a much higher figure than the 7·7 cents per gallon just referred to. The treatment of this tar by processes known to-day in America will result in the sale of water-white tar acids, solvent naphtha and neutral oils, but this raises the important question as to whether the power station engineer, working possibly in conjunction with a gas-distribution company, will consider it proper to include in his equipment a refinery for the production of marketable products from tar. If the refining profits be included in the revenue for tar, there is no question whatever that a high price may be established for the tar. If, however, it be deemed that the refining of tar should be the business of a chemical company separate and apart from power or gas station, then the gross trading profit of the refinery has to be subject to overhead charges and profit which will reduce the net value ex the carbonizing works by as much as 20 to 25 per cent.

TABLE 4.

Product	Amount and price	Revenue
		$
Gas ..	8 000 cub. ft. of 530-B.Th.U. gas at 30 cents per 1 000 cub. ft.	2·40
Tar ..	24 gal. at 8 cents per gal.	1·92
Light oil..	2·75 gal. at 10 cents per gal.	0·27
Coke ..	1 430 lb. at a price per B.Th.U. equivalent to that of the coal	1·73
	Total	$6·32

Even on the assumption that the refining profits are not to be credited to the power plant, it has been established in America that the net value at the carbonizing plant is in excess of 8 cents per gallon.

The low-temperature gas produced has a high heating value of approximately 830 B.Th.U. per cub. ft. and, therefore, to make town gas of 530 B.Th.U. per cubic ft. it is necessary to blend with this rich gas some diluent gas produced from the original coal, resulting in the production of a larger volume of the lower-grade gas per ton of coal treated.

The revenue from the pre-treatment of coal by low-temperature carbonization may therefore be set out to compare with the revenue from high-temperature carbonization, the latter based on the data given by Messrs. Knapp and McMichael. In Table 4 it is assumed that a certain part of a ton of coal is gasified to make water-gas to serve as a diluent for the rich low-temperature gas.

Table 4 gives particulars of the revenue from pre-treatment by low-temperature carbonization.

Comparing Table 4 with Table 3, it will be seen that the total revenue is 36 cents lower, a difference which is accounted for by the fact that with low-temperature carbonization no revenue is obtained from the sale of ammonium sulphate. With the prices now ruling for ammonium sulphate it is doubtful whether the revenue from this source is not practically balanced by the cost of recovery.

By low-temperature carbonization, therefore, it is possible to secure a net revenue for by-products at least equal to that of high-temperature carbonization and, further, to produce a solid fuel which would not only be acceptable to the power station engineer but would be preferred to raw coal for the reason that it is more readily combustible and can be burned at a greater rate per unit of combustion space with higher combustion efficiency.

One other possibility in favour of low-temperature carbonization is that of operating and capital costs being reduced as compared with those of a high-temperature system.

In designing and developing the McEwen-Runge process, the objective aimed at was a system which would have a very high capacity per unit, could be constructed cheaply, and could be operated with a minimum of labour. It was further decided that it would be necessary to produce town gas for sale.

The McEwen-Runge process has been described in various publications, but for the sake of clarity it may be well to repeat here some of its essentials. The process consists in carbonizing pulverized bituminous coal while that coal is in suspension in a hot gas. In practice the pulverized coal from the ordinary preparation plant of a pulverized-fuel-fired power station is intercepted on its path from the preparation house to the boiler house and is allowed to fall by gravity in a shower through a vertical tower up which heated gases rise, so that there is an exchange of heat from the gases to the coal, with the result that carbonization is effected. By this system it is possible to reduce the time normally required for carbonization from hours to seconds, making it possible to secure very high capacity from a relatively small plant. The resultant carbonized residue, being still in a finely-divided condition, is available for supply to the boilers, where it can be burned as pulverized fuel

One of the problems encountered at the outset was to devise a method of treatment on the lines just indicated which would result in the production of a final permanent gas rich enough to be suitable for town supply. It was known that if products of combustion were utilized as the heating medium and the coal were raised from atmospheric temperature to the carbonizing temperature with the unaided use of hot products of combustion, the resultant permanent gas would have a very low calorific value and would be useless except to be burned in furnaces.

As a result of extensive investigation and the preparation of a large number of heat balances, it was found to be theoretically possible to produce a permanent gas rich enough for town supply by including in the system pre-heating of the coal prior to carbonization, and by the introduction of heat exchangers which would serve to extract the sensible heat from the semi-coke and utilize the heat so extracted in the process of carbonization.

The plan substantially was to pre-heat the coal while in suspension in a vertical retort to a temperature of about 500° F., at which temperature it was assumed no valuable by-products would be lost and the coal would be merely affected to the extent of the removal of a certain amount of combined water and carbon dioxide. The pulverized coal at a temperature of 500° F. would then have to be raised, in the carbonization retort proper, to a temperature of 1 000° F. It was believed that the heat required to raise 1 lb. of coal through the first 500 degrees F. would be greater than that required to heat it through the second stage of 500 degrees, as the earlier stage was likely to be endothermic while the latter stage would be slightly exothermic. The reduction in the temperature of the hot semi-coke from 1 000° F. to about 300 or 400° F. provided, by means of the exchanger, a quantity of heated gas which had to be boosted in temperature by a fresh source of heat to provide the gaseous heating medium for carbonization.

FIG. 1.—General arrangement of experimental retort.

These possibilities having been established by calculations, it was then necessary to establish them by practical trial.

The first stage of the development was to determine that pulverized fuel could be carbonized by allowing it to fall in suspension through a vertical retort, and to obtain some data as to the rate of carbonization and the space which had to be provided for a given capacity. The first retort to be built is shown in Fig. 1. This retort was 30 ft. in height and 1 ft. in diameter and was operated over a period of several months, and it was established that pulverized coal could be efficiently carbonized at the rate of 200 lb. per hour. It served to prove that there need be no fear of the coal adhering to the sides of the retort to such an extent as would interfere with satisfactory commercial operation and, further, it demonstrated that the resultant semi-coke was in a condition suitable for direct firing in a furnace equipped for the combustion of pulverized fuel. It also provided sufficient evidence that the gases leaving the retort did not contain any excessive quantity of dust. In other words, it established the fact that it was possible to adopt this method of carbonizing pulverized fuel in suspension without any prohibitive loss in the form of dust, and that it should be possible to recover the condensable liquid by-products free from such dust as would impair their commercial value.

FIG. 2.—Arrangement of full-size retort.

The next stage in the development was to design and construct a large-scale commercial plant which, based on the factors established with the small plant, should be capable of carbonizing 200 tons of coal per day. The arrangement ultimately installed is shown in Fig. 2. It included an upper retort for the pre-heating of the pulverized coal to a temperature of 500° F. and a secondary or carbonizing retort which would raise the coal to 1 000° F., and below the secondary retort a heat exchanger which would serve to cool the coke and enable the sensible heat recovered to be returned to the system. The whole equipment was designed to be entirely automatic; the whole of the feeders, the temperature regulators and all other controls were centred in an instrument room so that one man could attend to the complete sequence of operations. The pulverized semi-coke from the heat exchanger was delivered to a pump and thence transported to the boiler house.

As might have been anticipated and, as is invariably the case in the development of all processes embodying some hitherto untried methods, a number of difficulties were encountered. In the first place it was found that the pre-heating of the coal to a temperature approximating to that desired resulted in the loss of valuable volatile matter. This required a great deal of investigation and a great deal of attention was devoted to this first stage of the process. The results are fully described in a paper read by Dr. Soule before the American Society of Mechanical Engineers in February 1928. The composition of the gaseous heating medium was varied over a fairly wide range. Gases containing different percentages of free oxygen were used, also gases which were neutral and contained no oxygen. It was finally concluded, however, that it would not be economic to heat the coal above 350° F., as beyond that temperature the loss of valuable volatile matter was greater than any benefit which could be derived from pre-heating.

Another difficulty which was encountered related to the operation of the heat exchanger, the object of which was to recover the sensible heat from the semi-coke. The heat exchanger originally designed became choked and, owing to the existence of a number of leaks difficult to detect and isolate, air was admitted which resulted in local combustion with the rapid destruction of the pre-heater elements. A very large number of changes were made until the engineers were driven to the conclusion that the cooling of the semi-coke was in itself a sufficiently difficult problem to solve without the added difficulty of endeavouring to recover the sensible heat from the coke. Ultimately, but not until after the expenditure of long and sustained effort, coke coolers were installed in which the cooling medium was water and the whole of the sensible heat of the coke was dissipated. It was found that unless the semi-coke was thoroughly cooled the problem of transporting it to the boiler-house bunkers was too great for practical solution.

Finally, therefore, the process was simplified in order to maintain continuous operation and obtain commercial results which would more clearly indicate the next stage of development. The two retorts were united and made into one. An independent coke cooler was installed in which water was the cooling medium, and by this means it was found possible to operate the plant over a long period and to transport pulverized coal continuously to the boiler house, where it was consumed in the boilers. It became clear from this operation that, while the semi-coke prepared in the manner described constituted an ideal fuel for the boiler house, permitting an increased rate of combustion per cub. ft. of combustion space and giving a high combustion efficiency, the permanent gas made was of too low a calorific value to be useful for public service. The actual value of the gas manufactured reached 275 to 300 B.Th.U. per cub. ft.

Having solved the engineering problems of showering the coal continuously through a vertical retort at a rate which gave the full estimated capacity of the retort, namely, 200 tons per day; having also solved the problem of cooling the hot semi-coke and having established that the semi-coke dust was an ideal fuel for combustion, it then became necessary to select the best method for increasing the calorific value of the gas and making it suitable for town supply.

Here it may be mentioned that the McEwen-Runge plant which was installed at the Lakeside station of the Milwaukee Electric Railway and Light Co. was in a favourable position to dispose of its gas, since the Lakeside installation was under the control of the North American company which also owned a gas works in the near neighbourhood, and it was the intention to supply gas in bulk from this McEwen-Runge plant had its quality been as suitable as was anticipated. As a result of the practical experience gained at Milwaukee and resulting from conversations with those in charge of the gas works, it became apparent that even had the plant functioned in accordance with the original plan and gas of the desired calorific value been obtained, the gas would still have been of doubtful value owing to its high specific gravity due to the large percentage of inert gas which it would have contained. It was necessary, therefore, to reconsider the whole problem of the composition of the gaseous heating medium, so that it would be possible to produce a gas not only rich enough as regards calorific value, but also one of a specific gravity which complied with the normal requirements of a public service company.

It was foreseen that this result was not beyond the bounds of possibility, since a very rich gas could be made by utilizing superheated steam as the heating medium. Alternatively, pre-heated blue water-gas could be utilized with or without the admixture of superheated steam. Other combinations have presented themselves and preparations are now in hand for the last stage of development, which is to secure a standard gas for public service.

There are one or two factors in connection with the pre-treatment of coal in conjunction with power generation which may be mentioned. It has been said that a pre-treatment plant should be capable of being operated at a varying capacity to suit the hourly demand for power, or alternatively that pre-treatment plant could only be applied to a base-load power station. This, however, is scarcely the case, since the pre-treatment plant can be operated at a uniform capacity per day of 24 hours, variations in demand for power being provided for by adequate storage bunkers for the pulverized semi-coke. This semi-coke can be stored indefinitely and is unlike pulverized raw coal in this respect. The variation in demand for town gas, which follows very closely the variation in demand for electricity, can also be provided for by adequate holder capacity. Seasonal variations can, of course, always be allowed for by having a sufficient number of units in the pre-treatment plant, one or more of which can be put out of commission during the season of light load.

It is an interesting fact that at the present time, in the large American towns, the demand for gas and the demand for electric power bear such a relation to each other that the demands are met by the yields of gas and power which it is possible to obtain by the pre-treatment of coal.

[The discussion on this paper will be found on page 229.]

LOW-TEMPERATURE CARBONIZATION OF FUEL, WITH SPECIAL REFERENCE TO ITS COMBINATION WITH THE PRODUCTION OF ELECTRICITY (GERMAN PRACTICE).

By Prof. P. Rosin, Dr.Ing.

(*Paper received* 12*th October*, 1929, *and read at a Joint Meeting of* THE INSTITUTION *and the* INSTITUTE OF FUEL, 21*st November*, 1929.)

SUMMARY.

The paper deals with the economics of the production of power and valuable by-products from brown coal, which is very plentiful in Germany but has an extremely low calorific value.

Germany's coal industry is characterized by the competition between two different fuels, namely, pit coal and brown coal. The pit coal is similar to that in England in its technical qualities, whilst brown coal represents a very inferior coal until it has been treated in order to improve its quality. It contains from 50 to 60 per cent of water and 3 to 10 per cent of ash, and its calorific value is only about 1 800 to 2 500 kg-cal. per kg. On the other hand, brown coal can be obtained so cheaply from very large open workings that its cost per calorie at the mine is much lower than that of pit coal. On account of its high water-content the transport of raw brown coal to any distance is uneconomic. Before it can be transported, therefore, it must be dried and converted into briquettes containing about 15 per cent of water. On the other hand, the transport of pit coal over long distances is rendered possible owing to low railway tariffs and favourably situated water-highways. For these reasons the production of electricity in Germany proceeds along two different lines. First there are the pit-coal power stations in the coal-bearing areas themselves, and in all those districts where no other economic fuel is available, that is, at the collieries and in most of the municipal electricity works. Secondly there are the brown-coal power stations in the immediate vicinity of the large open workings. The latter are being developed into very large power houses under Government or industrial control for overland distribution. As most of the German power houses have to operate with cooling towers, and as there are enough small rivers and streams in the neighbourhood of the brown-coal districts to supply a sufficient quantity of water, the main consideration in the planning of steam power works is the transport of fuel and electricity. On account of the low cost of production of brown coal, the power works using this fuel have in recent years gained a considerable advantage over those dependent upon pit coal. Whilst only 23 per cent of the electricity produced in Germany during 1914 in public electricity works was generated from brown coal, this percentage had increased in 1922 to 41 per cent and at the present day is probably over 60 per cent.

In 1913 the total energy production of public electricity works in Germany was only about 2 200 million kWh. This figure had, however, increased in 1927 to 12 400 millions, and in 1928 showed a further increase to a total of approximately 14 500 millions.* A similar amount of electrical energy is being produced each year in the industrial power plants, so that the total production in Germany this year will probably exceed 30 000 million kWh. This corresponds to about 500 kWh per head of the population. Of the 30 000 million kWh referred to, the public and industrial brown-coal stations produced about 10 000 millions, and for this purpose consumed from 25 to 30 million tons of brown coal. The six most important German electricity works using brown coal produced some 6 000 million kWh per annum, the plant installed in these works being of 2 050 000 kW capacity and consuming from 18 to 20 million tons of raw brown coal. This development will still further increase, for the tendency in Germany, as in England and America, is to concentrate production in large super-power stations having a high load factor and consequent low cost of production. Although the production of brown coal already amounts to 170 million tons a year, brown coal will still be available in Germany for several hundred years as a cheap fuel, whilst the cost of mining pit coal will probably become greater on account of the increasing depth from which it must be obtained, and the fact that underground working is becoming more expensive.

Although coal is plentiful in Germany the country is entirely devoid of natural oils, so that the study of low-temperature carbonization is of as much interest to Germany as it is to England. Dr. Heinze submitted to the Fuel Conference held in connection with the World Power Conference (1928) in London, a report† on the position of the German low-temperature carbonization processes. Although a year has passed since the publication of this report it is still quite up to date, as no new processes have been developed in the meantime. On the other hand, many very valuable technical and economic data have been collected during the last year in connection with the subject, owing to experience having been obtained from the operation of the new large brown-coal low-temperature carbonization plants which, having attained full production, are, taken together, now treating about 3 000 tons of raw brown coal per day, and the first really large low-temperature plant in the world has started in Wölfersheim. The data now available from these plants therefore enables the author to set out the German views and opinions of the relations between low-temperature carbonization and the production of electricity, as well as to forecast probable further developments.

---

* PEUCKER: "The Use of Brown Coal in German Public Electricity Works," *Braunkohle*, 1929, p. 572.

† HEINZE: "The Present State of Low-Temperature Carbonization in Germany," *Transactions of the Fuel Conference*, 1928, vol. 3, p. 1015.

The appreciation of low-temperature carbonization as an economic factor has undergone a considerable change in the course of the last few years. It was originally intended as a means of producing oil, low-temperature tar being the main product, whilst the semi-coke and gas were regarded as by-products. This view has undergone a complete change on account of the many disappointments and economic failures of low-temperature processes using German coal. German pit coal does certainly not contain sufficient tar for its sale alone to cover the cost of carbonization, and the author believes that this is true for all countries except in connection with Cannel coal, which is, however, only found in small quantities. The profit on the low-temperature carbonization of pit coal must therefore be derived from the sale of semi-coke. Besides being a smokeless lump fuel, it sells as artificial anthracite for domestic purposes at much higher prices than those obtained for raw coal. The economic basis of the low-temperature carbonization of pit coal in Germany is therefore the production of such semi-coke of high value from cheap slacks, and resolves itself into a question of the difference in value between the original coal and the smokeless lump semi-coke made from it, the calorific values of both being approximately alike. The value of the tar obtained from the low-temperature carbonization of pit coal, for which the price under most favourable conditions will not be higher than that of fuel oil or Diesel oil, is generally not sufficient to cover the capital charges and working expenses of the carbonization plant, and consequently the economic utilization of the gaseous products of distillation, which were formerly almost entirely neglected, is now attracting considerable attention. As it has a very high calorific value this gas should be a welcome contribution to the public gas supply, but up to now its utilization has not assumed any practical significance in Germany. It will be seen, therefore, that the production of oil from pit coal is now a secondary consideration, the main product being semi-coke for domestic purposes, with tar and gas as by-products. It is, however, considered that the gas will, in the near future, be looked upon as being of greater importance than the oil. The type of pit coal most suitable for low-temperature carbonization is therefore principally small coking coal containing over 6 per cent of tar, the caking characteristics being such as to enable lump semi-coke to be produced. Ranking far behind this comes the fine-grained non-coking pit coal, the tar percentage of which would have to be so high as to guarantee a profit by itself, as with this class of fuel the carbonization process improves neither the size nor the calorific value. However, this class of coal exists in Germany in small quantities only, but there are other classes of pit coal, also very limited in quantity, which, containing much ash, make a very poor fuel in the crude state, but which can be improved as regards their combustion properties by low-temperature carbonization.

As already explained by the author last year at the Fuel Conference in connection with the World Power Conference in London,* the co-ordination between low-temperature distillation and the production of electricity is only remunerative, generally speaking, if, on account of the revenue derived from carbonization, the cost per unit becomes less than when the most reasonably priced fuel which the electricity works concerned can purchase is used. This means that the initial cost of the complete combustion plant must be so low that the semi-coke burnt under the power station boilers will be cheaper than any other competitive fuel which the power works could use. A power station will never pay the same price for semi-coke as will the domestic market, and it does not necessarily require a large smokeless fuel, as it can produce current at a lower cost and in a perfectly simple manner from fine-grained raw coal, and could probably purchase and use those classes of coal which are unsuitable for low-temperature carbonization at a price lower than that which the carbonizing plants would have to pay for their supplies. An electric power station combined with a carbonization plant using pit coal can therefore only be considered economic if a non-coking coal contains so much tar and gas that its sale would cover all the capital charges and working expenses of carbonization, besides leaving an adequate profit without any increase in the fuel costs to the boilers. Hitherto such pit coal has not been found in Germany, and for that reason German pit-coal carbonization power stations cannot be operated on a remunerative basis until the initial costs of the carbonizing plant have been reduced to a fraction of those obtaining at present, or until totally different price conditions obtain in the oil market.

The low-temperature carbonization of pit coal in Germany is at present only possible for the production of semi-coke for domestic purposes, and the only progress made last year in this connection is the extension of the carbonizing plant at the Mathias Stinnes Colliery at Karnap, where two additional carbonization retorts have been added to the one originally installed, so that the whole plant now deals with a daily through-put of from 250 to 300 tons. This, the only large plant working economically in Germany, operates on the K.S.G. (Kohlenscheidungs-Gesellschaft) system, similar plants having also been erected, or being in course of construction, in England and America, so that it is not necessary to deal with details of them in this paper.

The independent pit-coal carbonization plants known to the author cost on an average £250 per daily ton of raw coal through-put, one ton yielding about 16 cwt. of semi-coke, the calorific value of which is approximately 7 000 kg-cal. per kg. If the power station operates with the highest fuel economy, 1 kg of semi-coke will at most produce 2 kWh, corresponding to 1 600 kWh per ton of carbonization coal. The installation of a carbonization plant in connection with a power station therefore means an increased capital cost of at least £3 5s. per kW installed, but in most cases even more. The whole of the charges due to this extra capital cost, together with the working expenses, would have to be covered by the profit derived from the tar and gas. For this reason all the important projects relating to low-temperature carbonization power stations using pit coal in Germany have had to be postponed, as they offer no prospect of remunerative operation at present, and only in special cases could non-independent carbonization plants directly connected to boilers be considered, the capital cost of which would not have to exceed about £75 per installed daily ton of raw coal through-put.

---

* P. Rosin: "The Possibilities of Co-ordination between Coal Processing and the Production of Electricity," *Transactions of the Fuel Conference*, 1928, vol. 8, p. 925.

In this connection it should be mentioned that a certain inferior slatey coal containing a high percentage of ash, for which there is at present no market, is found in the neighbourhood of Polish Upper Silesia. The combustion of this coal under boilers shows an efficiency of only 40 to 50 per cent, even with mechanical step-grates, whilst trials made on chain-grate stokers have shown that it is difficult to keep a fire alight at the arch, in addition to which the clinkering is very serious. Various mines (Prinzen-grube, Mittel-Laziska, Trautscholdsegengrube of the Prince Pless Mines administration, Kattowitz) have therefore adopted the method of utilizing this coal at their own power stations by means of the patent boiler furnaces combined with the carbonization retort developed by the Julius Pintsch A.-G. of Berlin,* from which primary tar is obtained. In this process the coal is carbonized in the apparatus installed in front of the boiler, from which it is discharged on to the grate where it is burnt. It is conveyed from the bunker through the carbonization shaft to the travelling grate. An exhauster draws part of the hot combustion gases out of the boiler furnace through the carbonization shaft and, in consequence of the reduction of pressure in the shaft, fresh air enters from the front, also producing hot gases owing to the combustion of a small part of the coal. These hot gases rising in the carbonization shaft carbonize the descending coal, their volume being adjusted by regulation of the fan. The residue, a kind of semi-coke, falls whilst still hot on to the chain grate and immediately commences to burn. The tar in the mixture of combustion and carbonization gases drawn from the carbonization shaft is condensed in normal water-cooled condensers, and the vapour-free gas mixture, which still has a calorific value of over 1 000 cal. per m^3, is conveyed to the boiler furnace and consumed.

On account of the fact that semi-coke falls upon the grate whilst hot and in a very reactive condition, the flame does not go out and combustion proceeds in a very satisfactory manner with an efficiency which, related to tar and steam, may be as high as 80 per cent.

The working figures are as follows:

Boiler heating surface ..	.. 550 m^2
Calorific value of coal ..	.. 4 500 kg-cal. per kg
Ash content of coal ..	.. 30–42 per cent
Coal charge	.. 80–100 tons in 24 hours
Average steam production	.. 28 kg per m^2 per hour
Evaporation figure ..	.. 4 to 5
Tar production	.. 7–7·5 per cent of the weight of coal
Average CO_2 contents of flue gases	14 per cent

It will be seen that in such plants it is possible to treat only non-caking pit coal over a 15-mm screen, brown-coal briquettes, or other fuel of similar size, not containing more than 20 to 25 per cent of water. Coking pit coal becomes too sticky under treatment to travel by gravity through the shaft, whilst with fine-grained material uniform carbonization cannot take place, on account of holes being formed in the column of fuel through which the hot gases flow, without carbonizing the entire mass of coal. Very wet fuel requires such an amount of heat that under certain circumstances there is no coke left for combustion under the boiler. With this equipment it is found that should, for any reason, the supply of suitable fuel for carbonization temporarily fail, the boiler can be fired with other types of coal until the normal supply for carbonization purposes is once more available. For this process grates are necessary which will convey the semi-coke in a glowing condition from the carbonization shaft into the boiler furnace, i.e. some type of travelling or chain grate. As regards boiler systems the inclined-tube type of boiler is the most suitable, because with these boilers the carbonization shaft can be constructed of a suitable height on account of the great height of the boiler, and any defective tubes can be replaced upwards, whereas in the case of cross-drum boilers such replacement must be done towards the front, which would necessitate the carbonization shaft being so constructed that it could be moved sideways. Naturally, this combination of carbonization with steam production is applicable only to boilers in base-load power stations. Approximately 5 000 m^2 of boiler heating surface are in use or in course of erection at the Upper Silesian mines referred to above.

The position as regards German brown coal is, however, quite different from that which applies to pit coal. Here the tar and not the coke is the main product of carbonization, as the value of the tar produced is more than 2½ times that of the coke. The composition of a brown coal which would be considered suitable for carbonization would be approximately as follows:—

Water	.. 45–55 per cent
Ash	.. 5–8 per cent
Tar	.. Over 7 per cent
Semi-coke	.. 20–25 per cent
Carbonization gas ..	.. 50–70 m^3 per ton

On account of the high water-content, carbonization must be preceded by some drying process in order to yield a high through-put from the expensive carbonization plant. This pre-drying is accomplished either in tube dryers with back-pressure steam of 1 to 2 atmospheres, or in rotary dryers heated by flue gas. A good brown-coal tar yields on an average the following:—

Benzol (gasoline)	.. 3 per cent
Solar oil (gas oil)	.. 2 per cent
Fuel oil	.. 65 per cent
Paraffin	.. 12 per cent
Tar coke	.. 4 per cent
Refined residues such as acid resins and creosote sodium	.. 8 per cent

As the raw coal is broken up previous to drying and as the dried coal breaks up still further during the carbonizing process, the semi-coke obtained will all pass through a 10-mm mesh screen. The whole of the ash of the raw coal is transferred to the semi-coke, so that the ash content of the coke is between 20 and 40 per cent, but it is a free-burning smokeless fuel. It has, however, a great tendency to self-ignition.

The gas from the carbonization of this fuel has a calorific value of 4 000 cal. per m^3, but in this condition it contains up to 40 per cent of CO_2 and 10 per cent of H_2S. If purified, however, its calorific value is 8 000 cal. per m^3.

Brown coal can be completely carbonized at 450°C. The higher the furnace temperature the more the tar is cracked, causing the tar yield to fall whilst the yield of gas increases, and at the same time the amount of low-boiling-point components such as light oil and benzol is increased, and a tar is obtained in which the waxes and resins have become decomposed, thus rendering its further treatment more easy. The old carbonization furnaces operated at temperatures of over 600°, whereas the new ones are not heated above 500° C. and give tar yields of over 90 per cent of those obtained in laboratory apparatus.

The carbonization industry in Central Germany is over 70 years old. In 1928 about 2½ million tons of brown coal were carbonized, giving 522 000 tons of semi-coke. This year it is estimated that a further 20 per cent increase is to be expected. The production of low-temperature tar from brown coal is expected to amount this year to over 200 000 tons. During the past few years there has been a very great increase in this industry, due to the extension of the Geissen furnaces, which now carbonize about 3 600 tons of raw coal daily. This year no new carbonization plants have so far been built or ordered in Germany, on account of the experience obtained from these new works. After some years of rapid expansion it is now necessary to call a halt, during which the newly erected plants must be adjusted for efficient operation and a close study of detail made. At the same time, the development of the market conditions has to be awaited and the effect of the sudden increase in production noted. Whilst the future development will be favourably affected, owing to the fact that the new hydrogenating processes enable brown-coal oils to be transformed in bulk into motor spirit, the position is not yet clear as to what effect the increased production of paraffin will have on the German market, which is now almost saturated by the present output. On the other hand, the gas produced has now been successfully purified by the elimination of CO_2 and H_2S, due to pressure washing, so that it can be used for town gas supply. The Edderitz mines near Koethen are now supplying the surplus gas from the carbonization plant to Dessau for the Continentale Gasgesellschaft, which is the first long-distance gas transmission of this kind and has been in successful operation for several months.

On the other hand, the marketing of the increased quantities of semi-coke produced by this means has now become a difficult problem. The original carbonization works sold their coke, which contained 20 to 25 per cent of water due to being quenched, in small quantities for domestic purposes. This fuel is used in special stoves in small amounts, more particularly by the poorer classes of the population. This source of disposal, however, cannot be further developed, but has, in fact, decreased somewhat in recent years. It has not, so far, been possible to make briquettes from brown-coal semi-coke on an economical basis and, in any case, such briquettes would not be very suitable for domestic purposes on account of the high ash-content. The gasification of the very fine coke breeze containing a high percentage of ash is also a difficult matter. It is, therefore, necessary to endeavour to introduce it as an industrial fuel for steam boilers or furnaces. Until recently there were no grates on which this fine breeze could be burnt efficiently, but recently suitable travelling grates have been constructed which give successful results.* Previous to the introduction of this new type of grate the burning of the coke in pulverized form offered the best solution for boilers and cement kilns, but this method can only be satisfactorily adopted if the coke is dry-quenched, as wet coke cannot be pulverized and re-drying increases the cost beyond economical limits. Dry quenching, therefore, has now been developed and it is interesting to note that this method obviates at the same time the dangerous tendency to self-ignition.† Even so, the pulverizing of brown coal semi-coke is by no means easy, as the output of the mills is less than when raw coal is being ground, in addition to which the wear and tear is very heavy. If used in the pulverized form in boilers, the high ash-content causes much more trouble than when the fuel is burned on grates, and this necessitates very efficient cooling of the combustion-chamber walls. It is also essential to make use of highly pre-heated air in order to ensure good ignition of a fuel so low in volatile matter as this. In order to avoid sintering and to allow the boilers to operate continuously for long periods, it is necessary to space the tubes farther apart than usual. If the fuel is burned on grates the expensive grinding plant is eliminated, clinkering troubles in the combustion chamber and sintering at the tubes are reduced, and moisture in the fuel is not so detrimental.

The use of the new large carbonization plants calls for an immediate solution of the problem of the disposal of waste liquor containing sulphuretted hydrogen, phenols and fatty acids in addition to ammonia. The authorities do not permit this waste liquor to be run to waste unpurified, but the author's recent work has shown one way of purifying it and removing the phenol content from it.‡

The necessity of reducing the capital cost and working expenses of plant in connection with the carbonization of brown coal is daily becoming more obvious, as the coal deposits which are rich in tar and can be obtained cheaply in open workings are now becoming exhausted. It is therefore necessary either to carbonize the brown coal containing a low percentage of tar which is available from open workings, or to adopt mining methods for obtaining the richer brown coals, in which case the cost is fully twice as great. The cost of the raw material is the most important factor to be taken into account in estimating the earning capacity of a carbonization plant, particularly as the fuel contains 50 per cent of water, which is not only worthless but requires the installation and operation of expensive drying equipment.

In the earlier part of this paper mention was made of the importance of brown coal to the German electrical industry. The large brown-coal power stations make use of a certain amount of coal in which the percentage of tar is such that its carbonization is well worth considering. On the other hand, there are the independent carbonization works which already have a surplus of semi-coke very difficult to dispose of. These works dry the coal in many cases by means of back-pressure steam previous to carbonizing, this back-pressure steam having by previous expansion produced more electrical energy than is required by the carbonization works for its own purposes. For this reason the idea has been conceived of establishing brown-coal carbonization power stations in which the coal would be wholly or partly carbonized previous to combustion, and better use made of its valuable tar contents than by combustion only. It will be seen, therefore, that this idea first assumed tangible form in Germany and was developed there for the first time on a large scale. The pioneer of this method is the Hessen-Frankfurt A.-G. (Hefrag) with its brown-coal carbonization stations at Wölfersheim. This was the first carbonization power station in the world, having been founded jointly by the Government of Hesse and the municipality of Frankfurt. The author has to thank the managing director (Dr. Czakó) of Wölfersheim, to whom he is indebted for the following particulars.*

Diagram of a combined steam and brown-coal carbonization plant.

The illustration shows the general process of a brown-coal carbonization power station. The raw coal drawn from open workings undergoes a process of preparation called the wet service. In the course of this preparation the coal is broken up and screened, and the coarse wooden and clay components are removed. Following this the coal undergoes a drying treatment in the course of which the percentage of moisture is reduced from about 55 per cent to 15 per cent. The drying is carried out in tube dryers heated by exhaust steam from back-pressure turbines of the power plant. After being dried the coal is freed from dust in a separating plant and goes to the carbonization furnaces where it is carbonized at about 500° C. These furnaces work on the retort principle, so that pure gas is obtained from the coal. This gas is first of all freed from tar by gradual cooling, condensation and electrical precipitation, after which the light vapours are scrubbed out in the benzol scrubbers. The gas from which the tar and benzol have been removed can then be used for heating the carbonization retorts themselves, the surplus being taken to the boilers as additional fuel, or it can be made available, after necessary purification, for gas supply in the immediate neighbourhood, or pumped through pipe lines to any convenient distance. When the gas is disposed of in the latter manner the retorts of the carbonizing plants are heated by producer gas made from brown coal, from which a further supply of producer tar is also obtained.

The new works have been erected by the side of an old brown-coal power station, and the present daily through-put amounts to 1 000 tons per day for the first instalment. Most of the coal is obtained by cable dredger in open workings and is brought by the mine railway in self-unloading wagons which discharge over the draw-off bunker. From the latter it falls directly on to low-lying conveyor belts which carry it over the inclined raw-coal bridge to the preparation plant. The wet-service plant consists of two parts, each of 700 tons through-put in 16 hours. The coal which is broken up here, screened so that it will all pass a 1-in. mesh, runs over an inclined wet-coal bridge leading at right angles into the bunkers of the dry service. From there it is distributed over the 5 steam-heated tube-dryers, each dryer having a heating surface of 1 820 m^2, the dust being extracted by electrical means from the vapours as they leave the dryers. The dry coal is then taken on an inclined-belt conveyor to the carbonization house, where it is first of all freed from dust (amounting to about 10 per cent) by means of air separators. In Wölfersheim there are 7 Geissen carbonization furnaces which have been supplied by the Kohlenveredlung A.-G., of Berlin, and the eighth will be erected by the end of this year.

* "New Brown-Coal Carbonization Works, coupled with Production of Electricity in Upper Hesse." Lecture delivered before the 70th Annual Conference of the German Association of Gas and Water Experts, Berlin, 10th June, 1929.

The report of Dr. Heinze, mentioned above, embodied a complete description of the Geissen furnace, so that it is unnecessary to enter into details here. It is an upright revolving furnace the heating surface of which consists of a cast-iron cylinder built up of separate rings which rotate slowly. Inside this cylinder is a stationary refractory casing up the inside of which the heating gases burn and then flow downwards between the refractory casing and the internal surface of the cylinder. The coal trickles slowly down the outside of the cylinder on the internal louvred surface of the outer casing. The daily through-put of a furnace is 60 to 70 tons of dry coal, corresponding to 120 to 140 tons of wet coal. From the raw gas the tar is extracted by means of gradual cooling and electrical precipitation, the vapour-free gas being then passed on to the benzol-extraction plant by means of a system of pipes running from the carbonization house. The light oil vapours are scrubbed with oil in vertical towers in the benzol plant, the purified gas then passing in its final form to the gas-holder which, having a capacity of 3 500 m^3, acts as a compensator to overcome any fluctuations in the supply and demand. From there it is conveyed along the same pipe bridge back to the carbonizing house, where a portion of it is used for heating the retorts, the surplus acting as additional fuel to the boiler house.

The tar collected in the condensers is conveyed through pipes arranged on the same bridge to the tar storage tanks, which consist of 5 large tanks having a total capacity of 2 700 m^3. From these the tar is loaded into tank wagons and sent away for treatment. Two small tanks having a total capacity of 300 m^3 are used for storing the light spirit. A coke-fed gas producer is used for starting up the plant and it also serves as a stand-by. The semi-coke, which is carbonized at a temperature of about 450° C., is very liable to spontaneous ignition and is dry-quenched by the Rosin process. Cooling is effected by an ample supply of air and a small quantity of steam or fine water spray, the coke being stirred the whole time, with the result that the oxygen in the air saturates the coke during the cooling process, thus making it quite inert. The cooled coke is lifted into the bunkers of the boiler house by means of a suction conveyor plant. In the boiler house there are 4 high-pressure boilers fired by means of pulverized fuel. Each boiler has a heating surface of 750 m^2 and produces steam at a pressure of 35 atmospheres and a total superheat of 400° F. The fuel supplied to these boilers consists of 80 per cent of pulverized coke, the other 20 per cent being the coal dust drawn off from the drying plant. The coke is pulverized in Babcock-Rema unit mills, each of which has a capacity of 4 tons per hour. There are two mills to each boiler, and each blows the dust directly into the furnace without intermediate bunkering.

The power house is equipped with two condensing turbines each of 5 000 kW capacity at 15 atmospheres, and two back-pressure turbines each of 6 500 kW. The total capacity of this first section of the installation is therefore 23 000 kW. The high-pressure steam enters the back-pressure turbines at 33 atmospheres, each turbine being equipped with two runners. In the first stage the steam is expended down to 2 atmospheres and is taken from there as the heating medium for the carbonization plant coal-drying equipment. It is condensed in the tube dryers and returned as condensate at 2 atmospheres to the boiler feed-water tank. In the other stage of the turbine the steam is expanded down to 15 atmospheres and then passes at this pressure into the 5 000-kW condensing turbines arranged behind. One of the back-pressure turbines is always kept as a stand-by so as to ensure an adequate supply of steam at 2 atmospheres pressure for the coal dryers, under all conditions of power-house operation. The condensing turbines are operated in accordance with the load. The low-pressure runner of the back-pressure turbine supplying the steam for the dryers is operated at a steady load day and night, thus taking over the base load of the station whilst the peaks are supplied by the condensing turbines. The current generated is transformed to 20 000 and 100 000 volts and distributed by high-tension overhead transmission lines. The erection of this complete plant was started in the spring of 1928 and completed in March 1929, and all furnaces are now in regular operation. The coal is brought to the station by trains and the wagons are discharged by opening the side doors. The raw-coal inclined bridge leads to the wet plant from which connection is made to the drying plant by means of a second inclined bridge running at right angles to the former. From the semi-coke bunkers the pneumatic conveyor leads past the carbonization house to the top of the boiler-house bunkers, which are some 40 m high. As load fluctuations in the boiler house are unavoidable an adequate coke supply must be kept so as not to interfere with the steady operation of the carbonization equipment. The coke storage is situated below the horizontal portion of the pneumatic pipe bridge and has a capacity of 1 500 tons. Suction nozzles are arranged at various parts of the pipe system so as to pick up coke from any part of the storage space.

All buildings are of steel-frame construction, and particular attention was paid to simplicity of design. The working rooms are adequately lighted by means of numerous horizontal light strips and large window spaces.

It is hoped that the foregoing explanation will give a clear idea of this, the first carbonization power station. Exact operating data are not yet available as the plant has not been at work for a sufficient period.

The following general remarks with regard to the basis of brown-coal carbonization power plants may be of interest.

The capital cost of a new raw brown-coal power station in Germany is about £12 10s. to £15 per kW installed. The addition of a carbonization plant would increase this capital cost by approximately £12 10s. to £17 10s. per kW, depending within these limits on the yield of semi-coke, its calorific value and the consumption of the power plant to which it is attached. On account of this high extra capital cost only base-load power stations can be considered as suitable for such combinations. Assuming that such a plant operates for 3 500 hours a year, a tar yield of 7 per cent from the raw coal makes the revenue from electricity about twice the tar value, on the basis of present tar and energy prices. In this connection it must also be remembered that the price of energy is much less subject to fluctuation than the price of tar. The market price of electricity is, in all probability, the most stable of all market commodities, whilst the oil market is subject to violent fluctuations. For this reason the profit from a carbonization power station must be built up in the first place on the basis of the supply of current, which must be ensured in such a manner that fluctuations in the price of oil would not endanger the general economic stability of the works. This confirms what the author said at the beginning of his report to the World Power Conference, namely, that the kWh is the main product of a combination of carbonization and power stations, and that the requirements of the electricity supply must be the dominant factor of the whole project.

The first carbonization power plant has shown the way to a remunerative combination of electricity production with low-temperature distillation of brown coal. This combination can be more or less close, within the limits of the reasonable balancing of steam, electricity and gas requirements of the individual portions. Theoretically, an extraordinarily close coupling of the individual portions of the plant is possible, enabling an exceptional economy of fuel to be obtained, together with full utilization of nearly all the products in a reciprocal manner. In practice, however, this coupling should not be based on too rigid lines, even at the cost of a somewhat higher heat consumption. Difficulties are unavoidable in all plants and the resultant losses affecting all branches of the works are not necessarily counterbalanced by the attainment of the highest possible thermal efficiency. For this reason, the carbonization power plant should in the first instance be a combination of carbonization and power production from the point of view of space and profit, the operating standpoint of the combined plant being a secondary consideration. This principle will have even greater significance when the coupling becomes a triple one, that is, when the carbonization plant, power station and gas works are combined, to which end Germany is at present making preparations.

[The discussion on this paper will be found on page 229.]

LOW-TEMPERATURE CARBONIZATION OF FUEL, WITH SPECIAL REFERENCE TO ITS COMBINATION WITH THE PRODUCTION OF ELECTRICITY (ENGLISH PRACTICE).

By E. H. SMYTHE and E. G. WEEKS.

[*Paper received* 1*st October*, 1929; *read at a Joint Meeting of* THE INSTITUTION *and the* INSTITUTE OF FUEL 21*st November, before the* EAST MIDLAND CENTRE 26*th November, and before the* TEES-SIDE SUB-CENTRE 4*th December*, 1929; *also before the* MERSEY AND NORTH WALES (LIVERPOOL) CENTRE 20*th January*, 1930.]

SUMMARY.

The paper opens with the statement that Great Britain is dependent almost entirely upon coal for the production of electricity, the amount of water-power available being comparatively small. This being so, the inauguration of the "grid" transmission system and the co-ordination of power production afford favourable conditions for combining the latter with the distillation of coal.

The development of the Babcock process of low-temperature coal distillation is briefly described. So far as the authors are aware, this is the only process of its kind developed in Great Britain. It is suggested that the electric power plant of the future will take in coal as its raw material, but will deliver, in addition to electricity, motor spirit, fuel oil, creosote, pitch and other derivatives of coal tar. A discussion of the actual results obtained from the coal distillation plant at Dunston-on-Tyne follows.

The plant was designed for the production of an ideal power-station fuel, low in volatiles and therefore smokeless, and for the recovery of the more valuable by-products consistent with the production of such a fuel. The broad result obtained is that 16 gallons of tar oils and $\frac{3}{4}$ ton of semi-coke are produced from 1 ton of Northumberland small coal. The paper goes on to discuss the potentialities of low-temperature tar and it is explained that investigation of this aspect of coal distillation is by no means complete. The field of research is said to be one which presents wide possibilities.

In conclusion it is claimed that a new situation exists in which a practical process of coal distillation has been evolved in conjunction with the generation of electricity, and that as a result a definite step forward in the better utilization of our most valuable national asset, namely coal, is now due.

A full description of the coal distillation plant at Dunston-on-Tyne is given as an Appendix to the paper.

The compact nature of the industrial areas of Great Britain and their nearness to each other are two of her physical characteristics, a third characteristic being her complete dependence for power production upon her mineral resources, which means, in effect, upon a cheap and ample supply of coal. Most other countries have the alternative of hydro-electric power to fall back upon in greater or less measure, but Great Britain has to face the fact that the amount of power available from that source is never likely at any given time to be more than 5 per cent of the total power requirements of the country.

The first two of the above characteristics, namely, the compact nature of our industrial areas and their nearness to each other, make it possible to envisage an interconnected electrical system for the whole country —the already well-advertised "grid." The third characteristic makes the economical utilization of coal in combination with the production of electricity of immediate interest. With the creation of the grid transmission system the efficiency of power generation is bound to improve steadily, quite apart from engineering progress, because of the higher load factor at which large "base-load" stations will work, and this condition of high load-factor operation is a feature favourable to the combination of the low-temperature carbonization of coal with the generation of electricity.

In the present paper the Babcock process of low-temperature coal distillation, with the development of which the authors have been associated, is described, together with some details of the results so far attained. So far as the authors are aware, this is the only process developed and in operation in Great Britain with the primary object of combining the low-temperature carbonization of fuel with the production of electricity. Later is given a summary of the conclusions which, in the authors' opinion, may be drawn therefrom.

It is rather more than 10 years since the experiment, as it then was, of distilling coal before utilizing the resultant semi-coke in a boiler furnace was first tried in one of the generating stations of the Newcastle-upon-Tyne Electric Supply Co. The declared aim from the outset was to combine a practical method of coal distillation with the generation of electricity, the main objects being (*a*) to utilize in a more economical way our most valuable raw product, coal, and (*b*) to cheapen the cost of a unit of electricity at the generating station. Right at the beginning of the investigation it was necessary to determine which of many processes suggested was likely to give the best result technically and economically, and, further, the general lay-out of a plant to deal with an entirely new set of conditions presented many problems which had to be solved before any real measure of success could be claimed. The present is not a suitable occasion for a detailed account of the numerous trials and experiments which were found to be necessary due to absence of data and lack of experience, but it will be readily understood that the difficulties were considerable and that their effective solution occupied a great deal of time. A practical solution was not, in fact, reached until after years of painstaking application on an extensive scale of the sometimes wearisome method of "trial and error."

The results eventually attained have, however, confirmed the soundness of the original idea of combining the distillation of coal at low or moderate temperature with the generation of electricity. In the first place, of all the manufacturing processes with which the combination of coal distillation appeared to be a practical possibility, none offered so clear a prospect of success as the large-scale generation of electricity, for few, if any, utilize coal in anything like so large a quantity at one spot. Moreover, in the boiler furnace no use is made, as such, of what have been termed the "high-value heat units" in the coal, namely, those contained in the volatile constituent, as distinct from the "low-value heat units," or those contained in the fixed carbon constituent. Further, electricity supply provides two conditions which are essential if the best results are to be obtained from a coal distillation plant, namely, all-the-year-round continuity of operation and high load-factor working. The supply of waste heat from the boiler flue gases, in addition to steam and electric current required for the working of the distillation plant, are all available at the site.

Present electric power plants take in raw coal and deliver electricity. In the process the whole of the valuable volatile constituent of the coal is consumed. The electric power plant of the future will take in the same raw material, but in addition to electricity it will deliver other useful commodities such as motor spirit, fuel-oil, creosote and pitch. Moreover, the combustion of semi-coke instead of raw coal will at least diminish the ever-present smoke nuisance, and it will be seen from what follows that smokeless fuel and the by-products just mentioned can be produced from the very grade of coal commonly used in power stations.

The analysis of the Northumberland coal which is being treated at the coal distillation plant at Dunston-on-Tyne and also used as the ordinary power station fuel is as follows:—

Analysis of the moisture-free coal.

	Per cent
Carbon	72·75
Hydrogen	4·98
Sulphur (total)	1·26
Nitrogen	1·28
Oxygen	6·96
Ash	12·77
	100·00

The moisture content of the coal varies between 6 and 10 per cent, and the volatile content when containing 6 per cent of moisture is 31 per cent.

The heating value of the raw coal as determined by calorimeter is given below:—

Coal with 6 per cent moisture.

Higher heating value, 11 574 B.Th.U. per lb.
Lower heating value, 11 178 B.Th.U. per lb.

Water-free coal.

Higher heating value, 12 321 B.Th.U. per lb.
Lower heating value, 11 898 B.Th.U. per lb.

The grading of the coal is as follows:—

Percentage retained on 1-in. sieve	= 1·92
Percentage passing 1 in.; ,, ½-in. ,,	= 27·81
,, ,, ½ in.; ,, ¼-in. ,,	= 22·28
,, ,, ¼ in.; ,, ⅛-in. ,,	= 21·85
,, ,, ⅛ in.; ,, $\frac{1}{16}$-in. ,,	= 15·92
Below $\frac{1}{16}$ in.	= 10·22
	100·00

The result of the treatment of this coal is the production of a semi-coke and gas and a variety of by-products, namely motor spirit, white spirit, creosote, pitch and certain low-boiling-point tar acids.

The analysis of the semi-coke is as follows:—

Analysis of the moisture-free coke.

	Per cent
Carbon	74·92
Hydrogen	3·07
Sulphur (total)	1·61
Nitrogen	1·59
Oxygen	2·41
Ash	16·40
	100·00

The average volatile content of the semi-coke is 14 per cent.

The heating value of the semi-coke determined by calorimeter is as follows:—

Semi-coke with 0·74 per cent moisture.

Higher heating value, 12 168 B.Th.U. per lb.
Lower heating value, 11 907 B.Th.U. per lb.

Moisture-free semi-coke.

Higher heating value, 12 258 B.Th.U. per lb.
Lower heating value, 11 997 B.Th.U. per lb.

The fundamental basis of the design of the plant is the production of an ideal boiler fuel and the recovery of the most valuable by-products consistent with the production of such a fuel.

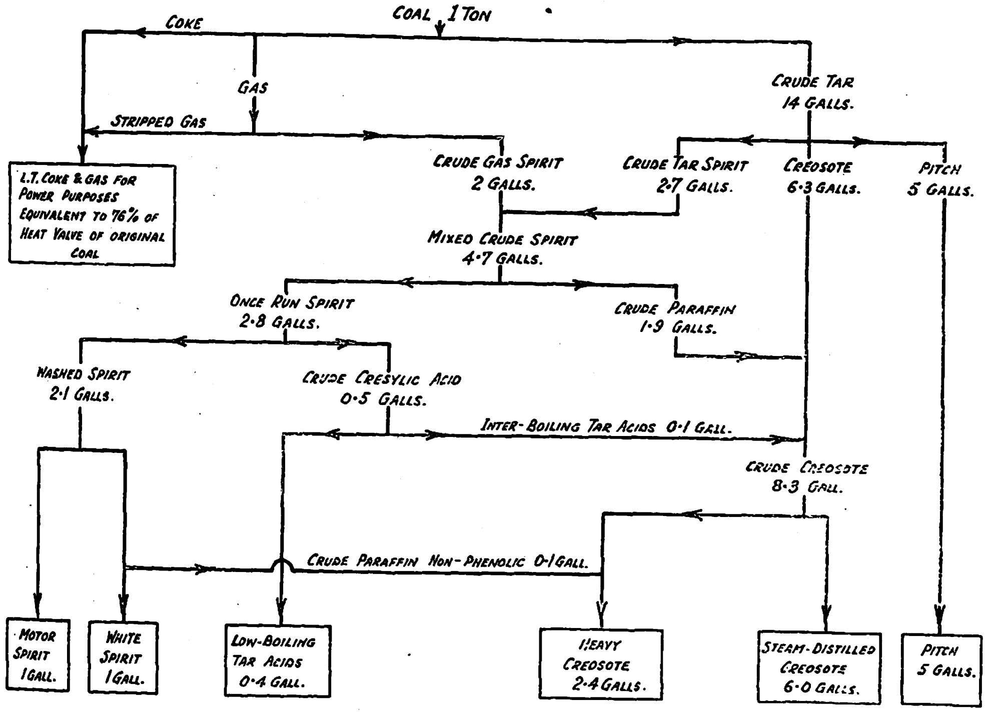
Experience gained in burning semi-coke either on chain-grate stokers or as pulverized fuel has shown that the best efficiency and ease of operation are obtained with a semi-coke having a volatile content of from 12 to 14 per cent. With a fuel of this nature all difficulties of ignition or burning-out are absent, but with semi-coke having a lower volatile content this is not so.

Difficulties have been experienced in maintaining efficient combustion with pulverized semi-coke produced by externally-heated retorts, and it has been ascertained that this is due to the overheating of the coal in contact with the retort walls, so that cracking of the hydrocarbons takes place and loose deposits of amorphous carbon attach themselves to the coke. The result is that in handling the coke and screening it, the outer surfaces of the larger pieces of coke suffer by abrasion, so that the "smalls" of the semi-coke contain a large proportion of graphite and graphite pieces which have a very high ignition temperature. This coke, when pulverized, may therefore require to be mixed with coal in order to maintain satisfactory combustion. In the case of the internally heated retort, however, the temperature of the charge cannot be higher than that of the distilling medium, so that no cracking takes place, no carbon is deposited on the coke surfaces in the form of graphite, and the resultant semi-coke has been found to be an excellent fuel for burning in pulverized form.

Experiments with pulverized semi-coke made by the Babcock process indicate that it is less hygroscopic than pulverized coal, and therefore where the pulverized fuel is used in the bin-and-feeder systems of pulverized-fuel firing there is less risk of trouble due to the fuel packing in the storage bins. Pulverized semi-coke is also less liable to spontaneous combustion than pulverized coal, owing to the lower volatile content and the absence of the lighter volatiles which have been driven off from the coal in the distillation process.

Apart from semi-coke, the result of the distillation of 1 ton of coal after treatment by the Babcock process is shown in Fig. 1, from which it will be seen that the by-products * available for sale after the smokeless fuel and gas have been used for steam-raising purposes are as follows:—

Motor spirit	1 gallon
White spirit	1 ,,
Steam-distilled creosote	6·0 gallons
Heavy creosote	2·4 ,,
Pitch	5 ,,
Air-blown low-boiling-point tar acids	0·4 gallon



COAL 1 TON
COKE
GAS
STRIPPED GAS
CRUDE TAR 14 GALLS.
L.T. COKE & GAS FOR POWER PURPOSES EQUIVALENT TO 76% OF HEAT VALUE OF ORIGINAL COAL
CRUDE GAS SPIRIT 2 GALLS.
CRUDE TAR SPIRIT 2·7 GALLS.
CREOSOTE 6·3 GALLS.
PITCH 5 GALLS.
MIXED CRUDE SPIRIT 4·7 GALLS.
ONCE RUN SPIRIT 2·8 GALLS.
CRUDE PARAFFIN 1·9 GALLS.
WASHED SPIRIT 2·1 GALLS.
CRUDE CRESYLIC ACID 0·5 GALLS.
INTER-BOILING TAR ACIDS 0·1 GALL.
CRUDE CREOSOTE 8·3 GALL.
CRUDE PARAFFIN NON-PHENOLIC 0·1 GALL.
MOTOR SPIRIT 1 GALL.
WHITE SPIRIT 1 GALL.
LOW-BOILING TAR ACIDS 0·4 GALL.
HEAVY CREOSOTE 2·4 GALLS.
STEAM-DISTILLED CREOSOTE 6·0 GALLS.
PITCH 5 GALLS.

FIG. 1.—Products for sale per ton (2 240 lb.) of coal distilled.

The value of the by-products on the basis of prices now obtainable in this country is as follows:—

Motor spirit	1s. 2d. per gallon
White spirit	1s. 0d. ,,
Air-blown low-boiling-point tar acids	1s. 8d. ,,
Steam-distilled creosote	8d. ,,
Heavy creosote	4½d. ,,
Pitch	2·84d. ,,

It will thus be seen that from 1 ton of coal costing 11s., by-products are produced having a value of 8s. 11d.

The distribution of 1 ton of coal after distillation may conveniently be summarized in the following form:—

	Weight	Heat value	Cash value (1 ton of coal = 100)
	per cent	per cent	per cent
Coke and gas for steam-raising purposes ..	76	76	76
Oils	7·36	11	81
Loss and used on process	16·64	13	—
	100	100	157

While the by-products mentioned above include those actually being made and sold at the Dunston distillation plant, they do not by any means represent the complete scope of what may be done to meet the requirements of the market. For example, it may be preferable to concentrate on the bulk production of any one product, thus reducing the amount of refining plant necessary.

---

* Commercial uses of by-products:—

Motor spirit.—For use in internal-combustion engines. The spirit possesses excellent anti-knock properties.
White spirit.—As a turpentine substitute for paint manufacture; for general use as a solvent; and as a cheap fuel for internal-combustion engines using heavy petrol or paraffin oil.
Steam-distilled creosote.—For the manufacture of special disinfectants, fungicides and weed killers. The residuals may be used as a "brick" oil or as charging stock in oil-cracking processes for the production of motor spirit.
Low-boiling-point tar acids.—For the manufacture of disinfectants, sheep dips, etc., also artificial resins and insulating compounds.
Heavy creosote oil.—For timber preservation; as a wash oil for benzol recovery plants; for the manufacture of disinfectants; for use as Diesel-engine fuel; and as charging stock in oil-cracking process for the production of motor spirit.
Pitch.—For cable-laying; for the manufacture of paint or varnish, and artificial resins; and for briquetting purposes.

Further, an alternative scheme for utilizing low-temperature tar oils is to subject them to cracking with a view to the production of motor spirit. Investigation has shown that by this means the tar oils produced at Dunston will give a yield of motor spirit amounting to approximately 30 per cent of the total quantity treated, the residue being available as fuel oil, in addition to residual coke of high calorific value. Activities of this nature will, of course, necessitate the installation of cracking plants specially designed for dealing with low-temperature tar oils.

Recent developments have rendered it possible to treat heavier oils containing a larger percentage of carbon than the natural oils treated by the cracking plants now widely established in the United States and elsewhere. There is therefore no reason for anticipating any difficulty in the way of recovering considerably larger quantities of motor spirit from low-temperature oils than is possible by other means, but here, again, an essential feature is that large quantities of low-temperature oils should be available as it is only possible to treat large quantities commercially.

A further outlet for the use of low-temperature oils is in connection with the hydrogenation of coal. It has been found that these oils constitute a suitable medium for mixing with the coal transformed by this process, and it is believed that considerable quantities of low-temperature tar oils are actually being used for this purpose in coal hydrogenation installations.

So much for results, actual and prospective. The coal distillation plant employing the Babcock process and installed at the Dunston power station of the Newcastle-upon-Tyne Electric Supply Co. is described in an Appendix to this paper. The next succeeding paragraphs summarize what has so far been achieved and offer some comment on the probable future, as the authors see it, of coal distillation at low temperature.

It is claimed that a new situation exists in which a practical process of coal distillation has been evolved in conjunction with the generation of electricity. This development has been carried out primarily for the better utilization of the constituent parts of raw coal, but there are also the prospects (*a*) of cheapening the unit of electrical energy, and (*b*) of providing a smokeless fuel which has proved itself to be eminently suitable for burning on a large scale in boiler furnaces. A good deal of success has recently been achieved in the direction of improving the combustion of raw coal, but all the energy has been confined to that one direction. Under the new conditions, the advance which has been made will be consolidated and combined with better utilization of the raw coal and the production of an improved boiler fuel.

The claim outlined above is based upon results obtained during three years of continuous operation under day-to-day working conditions. The plant has, moreover, two important advantages. In the first place it occupies little ground space, and secondly, as is shown by Fig. 6, it can be conveniently worked in with the design of the boiler-house plant of a modern power station. The further conditions of reasonable first cost, reliability and low working cost, have also been met.

It may be said that no details of first cost are given in the present paper. The attempt here made is to give a description, necessarily brief, of the plant and process as they exist to-day in practical form at the end of a long development. The expenditure on the existing plant, many of the details of which had to be designed as the work progressed, would form no reliable guide, but at the same time the experience gained has been such that there is no practical difficulty in the way of preparing a close estimate for a plant of any desired through-put. The capacity of the existing plant at Dunston is now being increased by the installation of a further retort capable of treating 60 tons per day, and this new retort will soon be in operation. A design has been prepared (Fig. 6) involving the employment of three separate retorts, each with a through-put of 160 tons per day.

The investigation of the commercial utility of the by-products derivable from low-temperature tar oils is by no means complete, and the field of research is one which presents wide possibilities. The position might, in fact, be compared with the state of affairs that existed in a number of industries, for example the gas industry, until chemical research led to discoveries which resulted in the birth of vast new industries solely concerned with the transformation of what were once regarded as waste products into commodities of essential value. The manufacture of aniline dyes, synthetic nitrates and synthetic resins are notable examples of what has been achieved in this respect, and it is not unreasonable to assume that important new uses will also be found for the by-products derivable from low-temperature tar as soon as larger supplies than have hitherto been possible appear on the market. The result of recent research work on these tars points definitely to further developments of commercial importance.

Having regard to the practical and technical efficiency here claimed for the process of coal distillation, it may be said that the progress made up to the present time, measured in terms of the tons of coal distilled per day, is disappointingly small. The fact must be admitted, but the explanation is fairly simple. The utilization of coal for power generation in the way advocated in this paper amounts, in effect, to a new industrial process, and new industrial processes are notoriously slow in establishing themselves against old and well-tried methods. For example, the operation of winning coal was for long years purely a manual process. So far as the actual process of coal-getting is concerned, the coal mines of Great Britain were worked almost entirely by man-power until the beginning of the present century. Even now there are few mines in which the coal is mechanically cut and in which its transport from the coal face to the pit bottom is worked throughout by mechanical means, a fact which may surprise a mechanical engineer used to handling surface transport problems. So it may well be with the fuel technologist of the not very-distant future. He will be unable to suppress his astonishment that for the first quarter of the twentieth century, during the development of the power industry into one of the most progressive industries in the country, measured either by physical growth or technical achievement, raw coal to the extent of many million tons per annum continued to be burnt under boilers.

The authors consider that the effective combination of coal distillation with the generation of electricity is already a practical and commercial possibility, and that by this means a decisive step forward in the direction of the better utilization of our most valuable national asset, namely coal, is now due.

APPENDIX.

DESCRIPTION OF THE COAL DISTILLATION PLANT AT DUNSTON-ON-TYNE.

The coal distillation plant at the Dunston power station is now in its third year of continuous operation. It is composed of two retorts, operating in conjunction with a Babcock boiler of 30 000 lb. of steam per hour evaporative capacity.

The general lay-out of the complete installation is shown in Figs. 2 and 3. Fig. 2 indicates the general features of the plant. On the extreme left of the lower portion is seen the cross-section of the boiler house. The dimensions of this house are 102 ft. long by 40 ft. wide and the height from the firing floor to the flat concrete roof on which are placed the boiler fans and chimneys is 52 ft. In the centre of the house, coal bunkers equipped with scraper coal conveyors are provided for the storage of coal or coke for use in the boilers.

The existing retort and boiler plant is located on the west side of the house and consists of one C.T.M. type boiler which is fitted with two Babcock and Wilcox compartment type chain-grate stokers supplied with hot forced draught obtained from a corrugated plate air-heater located immediately above the boiler. The two retorts (shown by thick lines) are located immediately in front of the boiler and are arranged to deliver coke to each stoker by means of enclosed screw conveyors. It will be noted that the space occupied by the retort plant is relatively small, about the same as is usually provided for the withdrawal of chain-grate stokers for repairs and overhaul. Hoppers for receiving ashes and riddlings from the stokers are located in a basement below the firing floor, and a standard Babcock and Wilcox vacuum ash plant with ash breaker is installed. The east side of the boiler house contains a Babcock and Wilcox pulverized-fuel boiler complete with a unit pulverizing plant of the Fuller-Bonnot type. This boiler, which has a heating surface of 5 486 sq. ft., is fitted with Luloff water-cooled walls in the sides and back of the combustion chamber and is surmounted by a feed-water economizer and plate type air-heater.

The pulverized fuel is fed into the combustion chamber through a standard Babcock and Wilcox Lodi type burner which receives its supply of hot air from the air heater on the top of the boiler. The pulverized-fuel boiler is at present being fired with pulverized coal, but provision has been made for this boiler to be fired by semi-coke on the completion of a new retort which is now in process of erection.

The top portion of Fig. 2 shows on the left the lay-out of the two existing retorts each of which are capable of treating 30 tons of Northumberland coal per 24 hours. The new retort already referred to is shown on the right-hand side of this part of the illustration. This new retort will be capable of handling 60 tons of coal per day and is therefore of twice the capacity of each of the existing retorts.

Semi-coke from the new retort will be transported by conveyors to the storage bunker over the pulverized-fuel boiler in the adjacent boiler house, and will then be pulverized and consumed in the furnace of the pulverized-fuel boiler. It is intended, therefore, that in the near future both boilers will be fired with semi-coke under two different systems of firing, i.e. the existing retorts will continue to supply coke to the chain-grate stokers of the stoker-fired boiler, while the new retort will supply coke to the pulverized-fuel boiler via a Fuller-Bonnot mill and Lodi burner. On the right of the lower portion of Fig. 2 is shown the side elevation of the new 60-tons-per-day retort plant. The new retort and its auxiliaries are shown in thick lines, while the existing building, coal bunkers and conveyors are indicated by faint lines. The boilers are designed to generate steam at 250 lb. per sq. in. pressure and a total temperature of 702° F. The steam is conveyed to the main power station, for use in the turbines, by an overhead pipe line as indicated on the site plan shown in Fig. 3.

The coal used in the process is similar to that ordinarily supplied for burning in the furnaces of the power station boilers and is obtained from several local Northumberland collieries. The coal is delivered by railway trucks to two hoppers from which bucket elevators lift it to the coal-screening plant, where the fines are removed and afterwards transported to other boilers in the power station by way of trucks on sidings, as shown in Fig. 3. In cases where the coal is suitable, screening may be dispensed with and the raw coal delivered direct to the retorts. The coal passing over the coal screen is conveyed by scraper conveyors to bunkers located immediately above the retort plants.

In the Babcock process the distillation of the coal is effected by passing hot gases in intimate contact with the fuel, no external heating being employed. This facilitates continuity in operation and renders possible the economic construction of large units of simple construction, with consequent low capital and operating costs. The method of operation is shown diagrammatically in Fig. 4. The coal, which is stored in bunkers, is dried and preheated before entering the retorts, as it has been found essential with certain coals to drive off the moisture and heat the coal before it enters the retort, otherwise the effects of condensation of the oil vapours in the retort gases may impede the flow of distilling gases through the coal. For this reason the coal, immediately it leaves the bunker, is passed through a preheater consisting of a chain grate enclosed in a brick chamber. The coal is conveyed in a layer approximately 3 in. thick on the chain grate, while waste flue gases at a temperature of 200° C. drawn from the flues of the boiler plant are passed through it, thus heating the coal by direct contact with hot inert gas.

The time taken to preheat the coal used at Dunston is approximately 15 minutes, and the preheating is carried out without effecting any distillation of oils.

FIG. 2.—General arrangement of low-temperature distillation plant at Dunston power station.

The use of flue gases in the first stage of the process in the manner described not only prevents undesirable condensation of oil vapours on the coal entering the retorts, but also effects an economy in the heat required to distil the coal, as the heating gases used in the preheater are practically waste gases from the boiler plant. The preheated fuel falls over the discharge end of the preheater grate into a hopper containing screw conveyors which feed the coal into a rotary coal-feeding valve which prevents leakage of gas between the preheater and the retort.

Each retort consists of a casing constructed of mild-steel boiler plate lined with brickwork where necessary. The upper part of the retort contains a device for feeding the coal on to the fuel bed and automatically spreading and levelling the incoming fuel by means of rotating scrapers which revolve at a speed of 1 r.p.m. The fuel bed is approximately 3 ft. deep and is supported on six slowly rotating rollers which fulfil the functions of a supporting grate and coke extractor. These extractor rollers consist of 6-in. square mild-steel shafts on which are fitted toothed wheels of non-growing cast iron, the teeth of which are spaced so that small spaces are left between the teeth of the adjacent wheels for the passage of the heating gases upwards through the coal. The rollers are operated by ratchets which are moved backwards and forwards by hydraulic cylinders. The lower portion of the retort forms a chamber for the reception of the heating gases and serves as a hopper into which the coke is continuously extracted prior to being fed to the stoker hoppers on the boiler.

Since the coke is used on stokers it is essential that large pieces of coke should be crushed down to a convenient size, and for this purpose a 2-roll crusher is provided in the bottom of the coke hopper. The crushed coke then passes through a rotary sealing valve into a screw conveyor which delivers it to the stoker hoppers. The screw conveyor traverses from side to side in the same manner as the well-known Babcock and Wilcox coal-distributing gear used on coal-fired stokers, and thus an even distribution of the larger and smaller pieces of coke is obtained in the stoker hopper. The screw conveyors are totally enclosed and are provided with water sprays which partially quench the coke before it reaches the stoker hoppers. The steam thus produced at the expense of the sensible heat of the coke is utilized in the manner described in the following paragraph.

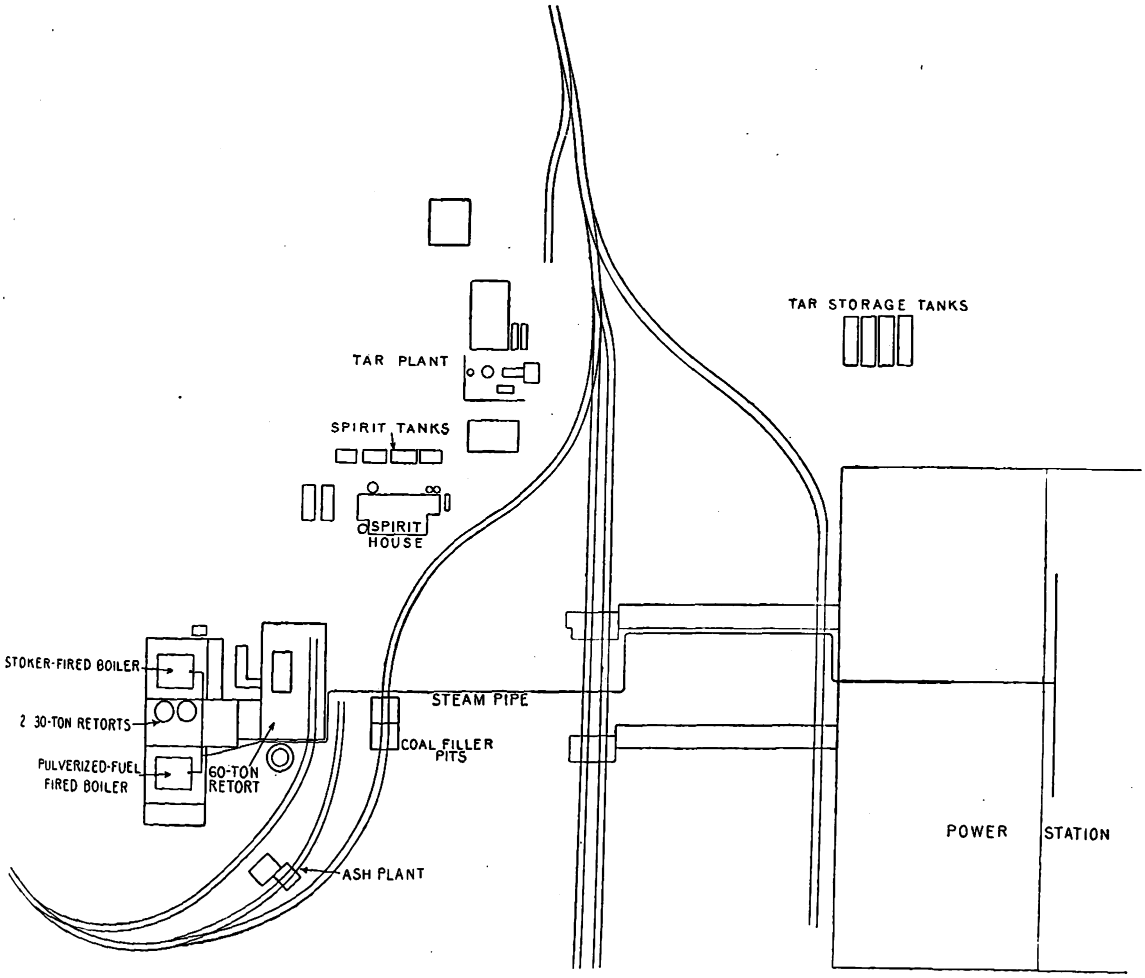

FIG. 3.—Site plan.

The distillation of the coal in the retorts is effected by passing a mixture of superheated steam at atmospheric pressure and combustion products at a temperature of between 600 and 700° C. into the lower hoppers of the retort and upwards through the fuel bed. No external heating of the retort is used which might be likely to cause overheating and consequent cracking of the oils evolved from the coal. The use of internal heating in the manner described ensures that the volatile constituents of the fuel are distilled and are carried off by the flow of gases at or below their temperature of evolution, and no volatile product is subjected to a higher temperature than that at which it was evolved.

FIG. 4.—Diagram of retort plant.

The maximum temperature of the fuel in the retort does not exceed 550° C., which represents true low-temperature distillation conditions.

The distilling medium is obtained by first burning a suitable fuel in a small combustion chamber located below each retort, and, when combustion is complete, sufficient steam at atmospheric pressure is added to produce distilling gases of the required composition and temperature. Reference has already been made to the quenching of the hot coke leaving the retorts by spraying water into the enclosed coke screw-conveyors, whereby steam is generated. Part of the steam required for the production of the distilling gases is obtained from the quenching of the coke in the manner already described, and the additional amount necessary may be obtained by bleeding the turbine casings at a point where the steam may be obtained at substantially atmospheric pressure. The hot products of combustion may be obtained by any one of the following methods, all of which are available at Dunston.

(1) Combustion of powdered fuel.
(2) Combustion of producer gas.
(3) Combustion of coke-oven gas.

A small amount of gas is given off by the coke in the coke-quenching screw-conveyors and this is utilized in the combustion chamber for assisting in the production of the distilling medium. In order that the steam and combustion products may be thoroughly mixed before entering the retort, they pass through a relatively long brick-lined duct which serves as an attemperating chamber. The time taken for each particle of coal to pass through the retort is approximately 3 hours, and the rich retort gas and oil vapours from the coal mixed with the distilling medium are drawn off from the upper part of the retort and passed through gas filters which clean the gas of dust before condensation and further treatment. The gas filter consists of chambers in each of which there is a bed of small coke through which the gas is filtered. Arrangements are made for the withdrawal of dust and coke from the bottom of the filter, and the admission of fresh coke to the top. The

dust-free gas is then passed to a water-tube condenser in which the gas is cooled and the tar vapours are condensed, the resultant crude tar being collected in a separating tank and then pumped to storage tanks for sale or further treatment.

A rotary gas exhauster shown near the condenser in Fig. 5 draws the gases from the retorts through the condenser and forces them through a tar extractor to remove the final traces of tar, and finally to a rotary gas washer where the gas is brought into intimate contact with wash oil which absorbs the spirit from the gas. The oil used in the gas washer may conveniently be a light creosote oil produced by refining the tar made in the process. After passing through the gas washer the gas, which has a calorific value of about 80 B.Th.U. per cubic ft., is piped to burners fitted to the combustion chambers of the boilers and burnt to assist the coke in the generation of steam.

The plant for recovering the crude light spirit from the wash oil is shown at the right-hand side of Fig. 5. The design of this part of the plant is generally similar to that which has been used for many years in gas works and coke-oven plants for the recovery of benzol, and presents no feature of special importance. The following is the sequence of operation:—Stripped oil is pumped continuously through the gas washer to absorb the spirit from the gas, and returns in a saturated state to the storage tank, while the saturated wash oil is also pumped continuously to the stripping plant in which the crude spirit is recovered for sale or further treatment. The plant for refining the crude tar and crude spirit from the gas for the production of the finished by-products, shown in Fig. 1, also follows the usual gas and tar works practice. The preparation of the finished by-products is preferably carried out in a separate plant located at some convenient distance from the power station, so that crude tar and crude spirit can be easily pumped over to the storage tanks which form part of the refining plant. The present plant has proved entirely satisfactory over a long period of working, but it is evident that to meet present-day conditions where power plants are increasing in size and it is the practice to install boilers of large evaporative capacity, retort units of very much larger capacity than 30 tons of coal per 24 hours are required for commercial operation. With this in view, designs have been prepared for single-retort units capable of dealing with 160 tons of coal per 24 hours, which it is considered would be a convenient size for use in conjunction with the size of boiler unit now coming into general use. In order to manufacture retorts of large size it has been found necessary to adopt certain modifications in the design, e.g. the cross-section of the retort is now of rectangular instead of circular section, with the result that the retort units can be more conveniently disposed in or alongside the boiler house and the cost of construction per ton of coal distilled is very much less. The cost of labour required to operate large units is also very much lower than with relatively small units. The method adopted for distilling the coal contained in the new 60-ton retort, as well as those now designed for even larger capacity is, however, identical with that already described, as practice has shown this method to be entirely satisfactory owing to its simplicity and the ease with which it can be controlled.

[The discussion on this paper will be found on page 229.]

DISCUSSION ON

"LOW-TEMPERATURE CARBONIZATION OF FUEL, WITH SPECIAL REFERENCE TO ITS COMBINATION WITH THE PRODUCTION OF ELECTRICITY."*

JOINT MEETING OF THE INSTITUTION AND THE INSTITUTE OF FUEL, 21ST NOVEMBER, 1929.

Mr. W. M. Selvey: A joint meeting such as this would at one time have been termed unique; and whilst it is unique from the sense of priority as regards these two important institutions, meetings of this kind are becoming increasingly necessary. On this occasion we have in active association the older high-temperature carbonization industry known as the gas industry, bringing with it the new low-temperature carbonization industry, and the electrical power industry. The fostering of the low-temperature industry by the high-temperature industry has only just begun, and in a tentative measure, and its fostering by the electrical industry is shown, in the papers presented this evening, to be coming about only in three places: at Wölfersheim, in Germany; at Milwaukee, in the United States; and at Dunston-on-Tyne, in the North of England. The fact that Dunston is in Durham is of very material interest, because Northumberland coal, and not Durham coal, is being used there. Dr. Rosin has covered admirably what may be called the philosophical side of the question. Are we to visualize a system which is (*a*) a dual co-operation of electrical supply with the chemical industry (distillation, etc.); (*b*) a triplex co-operation of electrical supply, the gas industry (rich gas) and the chemical industry; or (*c*) a quadruplex co-operation of electrical supply, the gas industry, the chemical industry, and the domestic fuel industry (the product of which latter is commonly referred to in the United States as "artificial anthracite")? Under heading (*a*), consider the paper by Messrs. Smythe and Weeks. Obviously this is the simplest type of co-operation to bring about, considering our rigid national type of organization; for instance, the chemical industry has received statutory protection against overlapping with the gas industry. It has long been known that the real profits in this co-operation are all in the direction of the working up of the by-products; for instance, in connection with the introduction of German coke ovens in England in the early days. In some cases, in Yorkshire, coke ovens were installed free of cost in exchange for 10 years' production of by-products. Hence, the dual co-operation is a proposition to cheapen electrical power by (i) bringing into the balance sheet a profit from success in a collateral activity; (ii) producing the raw material for the collateral activity from a cheaper form of raw fuel than had hitherto been possible (i.e. steam slack, as against gas-making and coking slacks). It might broadly be claimed that (ii), even alone, justified (i), should statutory restraint ever be sought by misguided persons to smother this scheme. Consider, also, the scheme at Wölfersheim, which fits the above particularly well, in that brown coal is the cheaper form of raw material. Here, then, is a possible explanation of our having been shown two such processes in actual practical operation. They have "graded up" a raw product. With regard to the triplex co-operation, Mr. McEwen states, in effect, that he must add to the simple system of power and chemicals a graded-up gas product, and immediately he has to balance the parallel requirements of gas and power. He will probably succeed, but here he has to his hand financial interests which own and operate, at the same time, gas and power undertakings. In this connection the far-sighted have already acquired chemical interests, so that here is, probably, the only real way of bringing such a scheme about—a common financial umbrella. It is obvious that such a scheme presents no real difficulties in a country such as the United States, with its comparatively unfettered private enterprise, but in this country, with its statutory companies operating power and gas, and chemical companies with Parliamentary protection, it cannot be expected, unless a new spirit comes about and legislation is conceived for furthering industry instead of being solely for the protection of the individual consumer or the preservation of the *status quo*. This would indeed be a revolution. When we consider a scheme of the nature of (*c*), in which domestic fuel is sold according to a variable market, when gas is sold to a gas company when and as it can take it, and the balance of unsaleable fuel, whether breeze or surplus gas, or gas of low calorific value, is used for power, to say nothing of working up the by-products, one is appalled by the change which would be necessary in the national habits before such a system could become general. It certainly could not be of much or primary interest to the power concern, and therefore whatever successful schemes may eventuate, which are in part of this type, are not likely to fall within the scope of this consideration. This does not mean that such schemes may not be successful in other directions. I believe that the authors would be generally in agreement with me in that respect. Dr. Rosin states that in Germany they are already moving from the dual to the triplex. Yet one constantly sees simple-looking economic balance sheets which assume that much of this could be effectively brought about.

Dr. A. T. de Mouilpied: I agree with Mr. McEwen and Dr. Rosin as to the necessity, on economic grounds, for a working alliance between the coal-treatment plant, the power station and the gas distributors. Dr. Rosin has called it, very aptly, a triple coupling; but he states that in the near future gas will be looked upon as of greater importance than oil. I cannot agree with this statement, because I think that the hydrogenation of the primary coal oils will ultimately be found to be the most profitable by-product outlet, at least in this country. Fundamentally, however, the important product is the semi-coke. The authors of all three papers adopt the basis of the equivalence of heat units in the raw coal and in the semi-coke. As Mr. McEwen expresses it, there is no appreciation in the value of the solid residue. It is true that the calorific value of the semi-coke is of the same order as that of the original coal; it is sometimes a little higher for the semi-coke, depending upon the amount of moisture in the coal, and also upon whether one is comparing " gross " or " net " calorific values, but, broadly speaking, the calorific values are much the same. The figures given in the paper by Messrs. Smythe and Weeks show that quite well. There has been evidence for a considerable time, however, that the semi-coke, when burning, gives off a good deal more radiant heat than the coal, and a comparative test has been made, under industrial conditions, of a parent coal and its semi-coke. So far as I know, this had not been done before. A coal was selected and treated in the Salermo retort, the basic principle of which is the external and progressive heating of small particles kept in continuous motion in a system of troughs and revolving paddles. This system produces a very homogeneous semi-coke, made at a low temperature (500–550° C.), in such a way that there is no overheating of the charge and no cracking of the vapours, which are at once removed with the gas. The normal volatile content is from 13 to 14 per cent, so that the coke has the desired ignitability and combustibility. The semi-coke does not suffer from the presence of graphite, which has been referred to in the paper by Messrs. Smythe and Weeks as characteristic of semi-coke made in some externally-heated retorts. Mr. Shaw, city electrical engineer at Worcester, gave facilities for a test to be carried out there this summer. The boiler used was a Stirling water-tube boiler, with a heating surface of 8 989 sq. ft., this being the main boiler at the station. The test lasted for 8 hours in each case, and the fuel was burned in the pulverized form. The coal used was Birch Coppice screenings, containing 10·9 per cent of moisture, 19·1 per cent of ash and 29·3 per cent of volatile matter, with a calorific value of 9 830 B.Th.U. per lb. gross and 9 375 B.Th.U. per lb. net. The semi-coke was made from it at Fulham, and this semi-coke, as burned, contained 1·72 per cent of moisture (for it had picked up some moisture when travelling from London), 26·4 per cent ash, and 14·1 per cent volatile matter. Its calorific value was 10 055 B.Th.U. per lb. gross and 9 790 B.Th.U. per lb. net. During the 8-hour coal test, 46 276 lb. of coal were burned and 296 251 lb. of water evaporated; of semi-coke, in the same time, there were burned 41 882 lb., and 309 246 lb. of water were evaporated. The weight of water evaporated per lb. of fuel from and at 212° F. was 7·796 lb. for the coal and 8·926 lb. for the semi-coke. This showed an increase in equivalent evaporation per lb., using semi-coke, of 14·5 per cent. Making the necessary correction for the higher calorific value of the semi-coke, in that particular test the latter was worth, therefore, for steam-raising purposes 12·2 per cent more per gross heat unit than the original coal, and 10·1 per cent more per net heat unit—which latter I consider to be the more desirable basis to adopt. Some explanation of the difference in the results with the coal and the semi-coke is to be found in the fact that the furnace temperature is 378 deg. F. higher for the semi-coke, while the boiler exit temperature was 33 deg. F. lower. There must have been more radiant heat liberated, and in the absence of smoke it was effectively used. This was, of course, an isolated test, and it is extremely desirable that this direct comparison should be repeated using, for the semi-coke, pulverizers and, particularly, burners adapted to its combustion. I offer these results as evidence to support the view that semi-coke has a higher value than that based on heat units only. If this were definitely established, it would have an important bearing on the economic aspect of the problem. The absence of deposit on the boiler tubes when using semi-coke must increase efficiency and save the cost of cleaning. With regard to the effect of distillation on the sulphur content of the fuel, the coal used at Worcester contained 2·27 per cent of sulphur, while the semi-coke contained 1·09 per cent, or less than half that contained in the coal. This reduction of 50 per cent, leading to a similar reduction in the amount of sulphur acid fumes emitted from a station, has a very direct bearing on a problem which is being much discussed. Can Dr. Rosin give some indication of his method of removing phenols from waste liquors?

---

* Introductory papers by Mr. McEwen (page 205), Dr. Rosin (page 212), and Messrs. E. H. Smythe and E. G. Weeks (page 219).

Dr. C. H. Lander: In comparing low-temperature carbonization as applied prior to steam generation for, say, electric power production, with low-temperature carbonization applied for the purpose of producing a totally different type of solid fuel, one finds the problem eased considerably in one direction (on the side of electric power), but in another direction made more difficult. The easing of the problem arises from the fact that it is possible to design machinery capable of very large " through-puts," which machinery should be cheap in capital cost and labour cost. On the other hand, there is no increase in the commodity value of some of the carbonization products, i.e. one heat unit in the product has only the cash value of one heat unit in the raw coal. For instance, to take an extreme case, supposing one installed a low-temperature carbonization plant at an electricity works, and burned the coke, gas and tar under the boilers, the result would be the expenditure of capital and labour to lose the heat units used in the process, with no compensating advantage. The next step, perhaps, is to install a plant on the lines of that referred to in the paper by Messrs. Smythe and Weeks, in which case there is little or no increase in the commodity value of the solid fuel produced by low-temperature carbonization as compared with the fuel with which one started. Therm for therm, it is substantially the same; there might be an increase of 5 or 10 per cent in thermal value, but the increased value is not nearly equivalent to 20s. per ton, as might be the case with solid fuel produced from cheap coal for domestic use. Again, the gas is burned under the boiler, and there is no increase of commodity value there. The engineers of generating stations which have been burning coke-oven gas say, quite definitely, that the gas is worth to them exactly its thermal value. Hence in this particular case one's activities are narrowed down to the stepping-up of the commodity value of the tar. If one obtains finished products from the tar, one obtains a greater commodity value, but it costs money to obtain the finished products. Mr. McEwen has pointed out the advantage of selling the gas, and the commodity value of the gas is raised if one can get gasworks prices for it. Trouble has been experienced in connection with the specific gravity of the gas. It is not recognized as widely as it should be that for gasworks purposes the specific gravity is almost equal in importance to the calorific value; if changes of specific gravity occur, the effect of the constancy of calorific value is upset, and modifications of burners become necessary. Mr. McEwen's paper shows that many difficulties have been overcome, but other difficulties, of a minor nature, have appeared as the work has progressed. Tests have recently been carried out on the plant at Dunston-on-Tyne; the report has not yet been published, but the figures obtained confirm absolutely the figures given in the paper by Messrs. Smythe and Weeks. I feel that there is a tendency, in connection with this subject, to accept any explanation as axiomatic simply by virtue of its constant repetition. Is it actually Mr. Smythe's experience that coke made in an externally-heated retort is more difficult to burn than coke made in an internally-heated retort? I have experienced no difficulty in burning in a pulverized form coke made in an externally-heated retort. In any case I doubt the validity of the explanation put forward. Certainly some cokes are more reactive, more easily burned, than others, and it has become customary to attribute this to the presence of graphite in the less reactive high-temperature cokes. Some years ago Sir William Bragg made some X-ray experiments on four types of coke—a metallurgical coke, a vertical-retort coke, an externally-heated low-temperature retort coke, and an internally-heated (superheated steam and gas) low-temperature retort coke. The tests were carried out most carefully, and the haloes which are characteristic of graphite were discovered in all four samples. Of course, the tests did not show whether the graphite was present in different quantities, but it is quite possible that the graphite had nothing to do with the results. However, by the ionization-chamber method, a measure can be obtained of the size of the graphite particles, and as the tests proceeded from the less reactive to the more reactive cokes, it was found that the size of the particles diminished. This might or might not be the correct explanation; there is as yet insufficient reliable evidence available to settle the point. It is particularly interesting to have confirmation by Dr. Rosin that the brown-coal problem is the one which is of the greatest interest to Germany in connection with low-temperature carbonization. Brown coal contains so much moisture that its commodity value as a boiler fuel is very low. It has to be dried: its commodity value is increased by the extraction of the moisture, and it is perfectly natural, when dealing with an absolutely non-coking coal, to go a step further and carbonize it.

Mr. H. Nielsen: With regard to the process described by Mr. McEwen, it seems to be wrong to grind the raw coal first and carbonize it afterwards, as this involves grinding from 30 to 35 per cent more material. After all, the quantity of heat generated in the boiler, weight for weight, by powdered raw coal and powdered residue was, for all practical purposes, the same. It has been found by experience over a considerable period, on quite large-scale working, that the grinding of the residue, i.e. a residue with no graphitic carbon deposit, shows a saving in power sometimes as great as 30 per cent over that expended in grinding the corresponding raw coal. Taking this into consideration, for a given amount of heat set free in a boiler one can effect a saving in overall power consumption in grinding of about 45 to 50 per cent. Therefore, it seems more satisfactory to carbonize the raw coal in its original condition, and then to cool and quench the residual fuel if so desired, since a residual fuel of some size can always be dealt with much more easily than a very finely ground, highly reactive powder. With regard to the paper by Dr. Rosin, I have been told that considerable difficulty has been experienced with the Geissen retort owing to the growth of the cast iron, and that in one or two cases the passage through the retort of the material to be carbonized had been almost stopped, owing to the growth of the metal having resulted in the closing up of the corrugations.

Mr. E. W. L. Nicol (*communicated*): The statement on page 206 of Mr. McEwen's paper regarding American practice and preference is no doubt correct, but it would be unfortunate if it were misconstrued as applying equally to this country. Business relations have, in fact, been established between several of the principal London electric and gas supply authorities for the purchase and supply of high-temperature coke as fuel. This business "alliance' is one result of the development of the sandwich system of firing coke, and the coke-burning mechanical stoker, and it has been maintained amicably to the mutual advantage of the parties, upon a fairly large scale, during the past 10 years. This fact tends to support the view that the development of combined gas-manufacturing and electric-generating stations is unnecessary in this country. The coal through-put of the Greater London gas supply authorities already exceeds 5·6 million tons a year; and quite a considerable proportion of the resultant 2·5 million tons of high-temperature coke is utilized by public electric and other power stations by means of mechanical stokers, either alone or blended with low-grade coal of a description that otherwise is often considered to be unsuitable for use with chain grates. Low-temperature coke is obviously more amenable to the pulverized-fuel system of firing steam boilers; but the question of facilitating or retarding the development of this system is no complete criterion for judging the respective merits of the high-temperature process of coal carbonization and those of the low-temperature process.

Mr. N. Prentice: (*communicated*): Can Messrs. Smythe and Weeks give the composition of the heating gases before the latter enter the retort? Only about one-half the volatile content of the coal is extracted, and the reason given for leaving the remaining 12 to 14 per cent is to ensure better use in the steam-boiler firing. Could not this large percentage be made use of for by-products if the resultant gas and coke were used in a Humphrey-type gas pump and Diesel-type pulverized-fuel pump and a water turbine, instead of a boiler and steam turbine? No credit is taken for sulphur or ammonia and the resultant sulphate of ammonia, which would increase the value of the by-products, and which are not available with straight boiler-firing.

THE AUTHORS' REPLIES TO THE DISCUSSION AT THE JOINT MEETING.

Mr. S. McEwen (*in reply*): Mr. Selvey's classification showing possible co-operators with a low-temperature carbonization industry prompts him to conclude that in the extended stage of his classification, namely, the quadruple co-operation of the electrical industry, the chemical industry, the gas industry and the domestic-fuel industry, an electric power company would not be materially interested. It may be said, however, that while such co-operation embraces a wide field three industries of the group fall within the sphere of public service, the power company being by no means the least important. This surely is sufficient justification for the power station engineer to occupy a prominent place in the development of means for the more rational utilization of our national fuel resources. Although Mr. Selvey seems impressed by the apparent impossibility of any working alliance between industries now entrenched and protected against each other, I would submit that the situation could be met by the establishment of coal "refineries" wherein the raw coal would be classified, cleaned, graded and carbonized, the products being supplied to meet the requirements of the four industries of Mr. Selvey's quadruple group. The adoption of the scheme for the provision of a gas "grid," now being considered, would remove the only barrier to the practicability of the suggested coal-refinery system.

The use of carbonized fuel, whether in lump or powdered form, for power generation, as one of the principal products of the "refinery," demands the interest and co-operation of the power engineer, and in this connection the claims made by Dr. de Mouilpied, as to greater value of a heat unit in the form of semi-coke as compared with a heat unit in the form of coal, are of interest. It would be of the greatest help to the commercial development of an industry for carbonizing coals at low temperatures, for the production of fuel for power generation, if a higher price per B.Th.U. could be established for semi-coke as compared with coal. I have said that there is no appreciation in the value of the solid residue, and there is certainly none comparable with the appreciation in value which results from the carbonization of coal to form a smokeless domestic fuel, and, while unhesitatingly admitting the accuracy of Dr. de Mouilpied's comparative trials, the results obtained do not directly yield data enabling me to appraise in monetary terms the benefit to be derived from the use of semi-coke. The power engineer, if asked to pay more per B.Th.U. for a ton of semi-coke than he pays for coal, will consider alternative methods of securing a similar benefit to that derived from the use of semi-coke. The comparative trials referred to by Dr. de Mouilpied show that with semi-coke as a fuel an efficiency, based on the net calorific value of the fuel, of 88·47 per cent was obtained while the boiler was operated at a capacity of 5·2 lb. of water from and at 212° F. per sq. foot of heating surface. Now it is known to the power station engineer that by a redistribution of heating surface presenting the maximum area to radiant heat, and by preheating the air required for combustion, it is possible to evaporate over 20 lb. of water from and at 212° F. per square foot and to obtain an evaporative efficiency of 90 per cent. With the development of steam-boiler practice a greater scope for improvement in results is offered than can possibly accrue from the substitution of semi-coke for coal. In the end the combustion of semi-coke will give better results than can be obtained from coal from the same boiler equipment, but the measure of the improvement can be stated in terms of the heating surface necessary for a given performance, and the increase in value of semi-coke to the power engineer over that of coal of an equal B.Th.U. content will not be greater than is represented by the annual charges for capital to be expended on additional heating surface, calculated in relation to the annual coal consumption. It will be found that such charges will not exceed 2 or 3 per cent of the value of the coal. In my opinion it is therefore desirable in preparing a prospective balance sheet for a low-temperature carbonization scheme for a power station to appraise the semi-coke at a value, per B.Th.U., equal to that of raw coal, and to rely on the distinct advantages which will result from its use to secure its ready adoption by power station engineers when the fuel becomes available.

Mr. Nielsen, in advocating the carbonization of raw coal in its original condition and the subsequent pulverization of the semi-coke for the preparation of powdered smokeless fuel, presents only one of the economic factors involved, namely, the relative costs of pulverization. There is, however, another factor which on balance is of much greater importance, namely, the cost of carbonization. For years the development work in low-temperature carbonization was confronted with the difficulty of securing a sufficiently high rate of heat transmission with the very low heat head it was possible to employ. For this reason operating and capital costs attained a very high figure, the capacity of low-temperature retorts being relatively low. By the method of carbonizing pulverized coal in suspension, an enormous heat-absorbing surface is exposed to the source of heat, and thus one of the factors for a high rate of heat transmission is at its maximum. In practice it has been proved that the carbonization of powdered coal in suspension is effected in a period of a few seconds, whereas the carbonization of lump coal requires several hours. Such a high rate of heat transmission made it possible to overcome the handicap of low temperature head and secure a high capacity from a single retort with the attendant low charges for operation and capital. The extra cost of pulverizing involved in the process described is only a fraction of the saving obtained as compared with the cost of carbonizing raw coal in its original form.

Mr. Nicol expresses the fear that my statement that coke produced by high-temperature processes is not favoured by power station engineers in America might be assumed to apply to power station engineers in this country, and in my opinion, while my paper dealt specifically with American conditions, the application of my statement is not limited geographically but is substantially true for all countries. The use of coke breeze, a waste product from high-temperature carbonization plants, is adopted for power generation in any country where its price is sufficiently lower than that of raw coal to compensate for the limitations which such fuel imposes on a steam-generating plant. Although, as Mr. Nicol states, the consumption of coke, presumably in the form of breeze, by power stations is considerable from the gas manufacturer's point of view it is inconsiderable when compared with the quantity of raw coal consumed for power generation. Power station engineers would not purchase high-temperature coke in any form if raw coal of a similar calorific value were available at the same price per ton. This being the case, it follows that high-temperature coke is not favoured by power engineers. Low-temperature coke can make reasonable claims to the favour of power engineers.

Dr. P. Rosin (*in reply*): The method adopted for treating carbonization liquor applies especially to the removal from brown coal effluent-water of phenols and fatty acids, which are somewhat different from the bituminous-coal phenols. The method consists in thoroughly pre-drying the coal, then destroying the sulphuretted hydrogen (H_2S) by sulphur dioxide (SO_2) and extracting the concentrated phenols and acids by a multiple-effect scheme. This extraction follows the example given by the Emscher Genossenschaft for removing phenols from coke-oven liquors, except that a percentage of certain insoluble tar bases is added to the extracting benzol. I would emphasize the great importance of pre-drying the carbonization coal, in order not only to diminish the effluent-water nuisance but also to increase the throughput of the carbonization furnaces.

As to Mr. Nielsen's question, the difficulties due to the growth of the cast-iron rings in the Geissen furnace have been overcome by thoroughly controlling the temperature. Moreover, special steels, such as nichrotherm, a heat-resistant steel containing nickel and chrome, have shown advantages as compared with cast iron.

Messrs. E. H. Smythe and **E. G. Weeks** (*in reply*): In reply to Dr. Lander's criticism of our remarks concerning the semi-coke produced by externally heated retorts, this was the only matter referred to in the paper of which we had not actual experience, and the statement was based on a series of experiments conducted in Germany and reported to us. We should be only too pleased, however, to compare notes with Dr. Lander, and are quite ready to be convinced by him of our mistake.

With regard to Mr. Selvey's remarks in connection with the use of Northumberland coal, the Dunston carbonization plant was designed primarily to operate with the type of coal used in power stations for steam generation, and although it is situated in the county of Durham it is at the extreme north of that county and is thus close to the South Northumberland coalfield, which produces steam coals of the class normally used in power stations. For this reason the Dunston plant is normally operated with Northumberland non-coking steam coals, and the results given in the paper are based on experience gained with that class of coal. The coal produced in the county of Durham is, as is well known, the finest coking coal in the world and, as such, is in great demand for the high-temperature carbonization industries and usually commands a higher price than non-coking steam coal, with the result that coking coals are not in general use in power stations and are not, therefore, of immediate interest for low-temperature carbonization in combination with the production of electricity.

In connection with Dr. de Mouilpied's statement as to the increased evaporation obtained in a steam boiler when fired with low-temperature coke, compared with the results obtained for similar tests made with the parent coal, we would say that our experience with boilers fired with chain grates and burning low-temperature coke has shown no appreciable increase in evaporative efficiency. It was interesting to hear a similar statement by Mr. McEwen, who has used pulverized low-temperature coke for firing boilers. In view of the fact that boilers burning coal now attain efficiencies of 90 per cent and over, it can hardly be conceived that an additional 9 or 10 per cent efficiency would be obtained by converting the fuel from coal to low-temperature coke. Dr. de Mouilpied also refers to the percentage of sulphur contained in the low-temperature coke as being half that in the parent coal. Our experience shows that no hard-and-fast rule can be laid down for the reduction in sulphur content, as it varies widely with different coals. In certain instances the reduction in the percentage of combustible sulphur in the coke approaches the figure mentioned by Dr. de Mouilpied, whilst in others there is no appreciable decrease. It is important that any figures given for sulphur content of coal or coke should clearly show whether the laboratory determination has been made for " total sulphur " or " combustible sulphur," as any confusion in this respect may lead to entirely erroneous conclusions.

With regard to Mr. Prentice's inquiry as to the composition of the heating gases before the latter enter the retort, these gases are a mixture of low-pressure steam and combustion products at a temperature of about 650° C. The average composition by volume of the heating gases entering the retort is approximately as follows: steam 46 per cent, carbon dioxide 3·2 per cent, oxygen 4·8 per cent, nitrogen 46 per cent. Mr. Prentice suggests that the large percentage of volatile matter left in the low-temperature coke might be made available as by-products, presumably by completely distilling the coal at a high temperature in order to reduce the volatile to a very low figure. If our understanding is correct, Mr. Prentice's suggestion is equivalent to ordinary high-temperature carbonization and in this connection it might be noted that the yields of by-products from high-temperature carbonization are not higher than from low-temperature carbonization, except that there is an increased yield of gas and sulphate of ammonia. High-temperature carbonization is not remunerative unless a price is obtained for the gas in excess of that which a power supply undertaking could afford to pay for gaseous fuel, and in view of the recent developments in the manufacture of synthetic ammonia the recovery of sulphate of ammonia from coal is far from attractive. With regard to the use of Humphrey pumps and Diesel engines plus water turbines, we submit that while these might produce power at high thermal efficiency they are not at present available in sufficiently large units to meet the requirements of the modern electric power station.

EAST MIDLAND SUB-CENTRE, AT NOTTINGHAM, 26TH NOVEMBER, 1929.*

Mr. L. M. Jockel: On page 220, in Messrs. Smythe and Weeks's paper, reference is made to the lack of utilization in the boiler furnace of the "higher value heat units" in the coal from the volatiles; but this cannot always be assumed, and depends to some extent upon the constituents of the volatile matter. Fuel technologists are now agreed, I think, that two coals of similar ultimate analysis, when heated to the same temperature, may behave differently in practice both as regards the yield of volatile matter and the nature of the coke formed. Although the subject has not been fully investigated, it would seem that the yield of volatile matter is dependent on the presence of certain constituents which are rich in oxygen. In regard to the gas firing of boilers, the efficiency is naturally affected to some extent by such considerations, and from experience I can say that gas firing is not always a very efficient proposition. On the same page, the higher and lower heating values of coal and coke are referred to, and very exact calorific values are given. I should like to ask the authors what is meant by the expressions "higher" and "lower" heating values, as, of recent years, the Institution of Civil Engineers has definitely laid down standard expressions for calorific value and thus ruled out any ambiguity in regard to the old methods of stating heating values on a higher or lower basis. Calorific values should be stated to the nearest ten, as the accuracy of the Mahler bomb is only about ± 0·5 per cent in practice. It is a particularly interesting fact that the calorific value of the semi-coke, quoted on page 220, is almost as good as that of the raw coal treated. Is the sulphur content always higher after low-temperature coking than the content in the raw coal? I gather that ammonium sulphate recovery is not worth while at low temperatures. Unfortunately no costs are given in the paper, but it is difficult to see, at present, how the cheapening of a unit of electricity can be effected by low-temperature carbonization plant with fairly cheap coal, although, of course, fuel prices will undoubtedly increase during the next few years. Can Messrs. Smythe and Weeks give us particulars of space required by the Dunston plant, expressed, say, as weight of water evaporated per hour per sq. ft. of floor area?

Mr. F. Nicholls: Undoubtedly we shall eventually have to carbonize our coal instead of using it in the present way. From an electrical engineer's point of view the plant appears to be very simple, and from an operator's point of view it is not very difficult to operate, so that the power station engineer need not be afraid of such a plant. The price which can be obtained for the oil will be a determining factor as to whether it is worth while working such a plant to produce oil. It would be interesting if Messrs. Smythe and Weeks would give us some information on this point; i.e. regarding capital charges, and maintenance costs per ton of coal used. They have pointed out that they have had no trouble with the preheaters; it occurs to me that they would be troubled with fires from waste gases, and might also suffer from temperature variations. What is the volatile content in the coke fed to the boilers at Dunston, and why is it proposed to use pulverized coke in the newer plant, and not coke, as at present?

Mr. W. Pearson: The desirability of recovering the valuable constituents of the coal used in generating stations is admitted; but, with industry controlled as at present, the determining factor is overall cost. I would ask Messrs. Smythe and Weeks whether the margin at present available for return on the capital expended on the additional plant is great enough to afford a reasonable prospect of financial success when a large proportion of the coal used in generating stations is treated in this way, with consequent reduction of the prices obtainable for the by-products.

Mr. F. Dransfield: One sees in this paper the beginning of the end for power station engineers. Electricity will be generated in the future from the waste products of other industries, and one can visualize public or private concerns supplying the requirements of a community for electric power, gas, steam, smokeless fuels and liquid fuels from one co-ordinated plant. People with vision are attacking the various phases of the problem, and, although at the present moment one does not expect these experimental plants to pay on a commercial basis, it is interesting to find that the Dunston plant in its developed state is yielding a profit on its working costs. I am pleased to see that the plant is simple and easy to operate; but, speaking as an operating engineer, one could wish for a neater lay-out for the sake of general cleanliness and ease of maintenance. Why is it proposed to change over to pulverized-coke firing instead of stoker firing in the newer plant? Is it purely for the sake of experience, or have difficulties arisen with the coke-fired stoker? The coal in the coalfields of this district has a high ash and moisture content, approximating up to 20 per cent in each case, and, by virtue of the nature of the ash, would present difficulties in cleaning. Would coal of this nature lend itself to treatment in the authors' plant or in the plant where the carbonization takes place in the pulverized form?

Mr. C. A. Brearley: Can the system described by Messrs. Smythe and Weeks be extended to the production of semi-coke for domestic fuel? In general, modern power stations already burn their fuel with a high degree of efficiency, and the cost of carbonization, in comparison with the value of the residual fuel, is much higher for industrial than for domestic coal. If, therefore, the process can be made advantageous for power-producing fuel, there would appear to be a much wider margin for its exploitation in the domestic fuel market. The claim, on page 220, that the combustion of semi-coke instead of raw coal will diminish the smoke nuisance, seems scarcely justified—at least in reference to efficient power stations—since the analyses quoted show an increase of the order of 25 per cent in both ash and sulphur content.

Mr. C. D. Wilkinson: I should like to point out that the most valuable of the by-products are the spirits, and also to know whether there is a satisfactory cracking process.

Mr. W. Wyness: Has the coal to be graded, or can it be put into the retort in any size? Also, can the plant be graded or reduced as regards intake or output?

---

* The paper by Messrs. Smythe and Weeks (see page 219) was the only introductory paper read at this meeting.

Mr. R. C. Woods: I notice that the plant is arranged to supply only that quantity of fuel that is required for the steam generators, and yet Messrs. Smythe and Weeks claim smoke abatement. I do not think that there are many generating plants which produce much smoke. Is it proposed to sell the fuel? The by-products seem to be very much less valuable than claimed by the Press. Are they very different? Would income from the sale of the by-products pay for the treatment?

Messrs. E. H. Smythe and **E. G. Weeks** (*in reply to the Nottingham discussion*): As regards the remarks of Mr. Jockel, the term "higher value heat units" refers to that portion of the coal which in the form of oils has a higher market value per B.Th.U. than the raw coal. If these oils are burnt in the boiler furnace they are not being used to the best advantage. It is agreed that two coals of very similar ultimate analysis may behave differently under low-temperature distillation conditions, but it is not a difficult matter to determine by laboratory assay the suitability of each coal for treatment and to estimate the yields of oils and other products which may be obtained in practice. The low-grade gas made at Dunston is fired under the boiler because this is the most convenient method of utilizing it in that plant. In other installations it might be found advantageous to utilize this gas for generating combustion products for preheating the coal, and/or heating the retorts. The best method of using the gas must be determined for each individual case. The calorific values of the coal and coke are determined in the usual manner adopted in the carbonization industries, and are not calculated in accordance with the special methods recommended by the Institution of Civil Engineers. The calorific values are the result of a rather too accurate conversion from the "calories" in which they were determined, to British thermal units. We agree that they should have been stated to the nearest ten. The sulphur content of the coke compared with that in the parent coal varies with different coals. In some cases the percentage of sulphur in the coke is equal to, or greater than, that in the coal, whilst in others the percentage of sulphur in the coke may be as low as half that in the coal. This wide variation is to some extent due to the chemical composition of the sulphur. Under low-temperature distillation, the recovery of ammonia in the form of ammonium sulphate is not worth while, as the yield does not warrant the installation of the relatively expensive apparatus required. The floor space occupied by the low-temperature retort plant is approximately the same as that required for the boiler which it serves.

In reply to Mr. Nicholls, there has been no trouble at Dunston with fires in the preheaters which are heated with waste flue-gases from the boiler. It will be appreciated that in normal operation the oxygen content of the waste boiler flue-gases is small and that therefore the danger of firing the coal is very remote. The control of the preheating temperature is easily effected, as the temperature of the waste boiler-gases remains constant within reasonable limits. There is no possibility of the combustible retort-gases finding their way into the preheaters, owing to a simple sealing device in the form of a rotary valve which isolates the preheater from the retort. The average volatile contents of the semi-coke fed to the boilers is 14 per cent, as mentioned on page 220 of the paper, and experience has shown that this percentage gives the best results in practice.

As regards the financial aspect of the process referred to by Mr. Nicholls and Mr. Pearson, it is agreed that this is dependent on the cost of installing and operating the process and on the market value of the by-products. The cost of installation and the operating costs are to a considerable extent dependent on the size of the plant and the quantity of coal handled by each unit, and it is therefore impossible to give a definite figure which would apply under all circumstances. It may, however, be assumed that if the semi-coke is used as a boiler fuel and is credited at the same price as the coal, it would be uneconomical to treat any smaller quantity than 100 tons per day, whereas the cost per ton of installing and operating a plant capable of treating 300 to 400 tons per day would be very much lower. On the other hand, if the fuel produced were intended for domestic use, it might be worth while to install smaller units. Assuming, however, the case of a plant capable of treating, say, 400 tons a day of coal costing 11s. to 12s. per ton, then, on the basis of the value of the by-products given in the paper and now obtainable in this country, there would be a reasonable margin of profit after due allowance is made for first cost, maintenance and depreciation. The reasons for the use of pulverized coke in the newer plant are given below, in our reply to Mr. Dransfield's remarks.

Mr. Pearson assumes that large-scale operation will necessarily result in a reduction of the price obtainable for the by-products, but experience in other directions has shown that this is not inevitably the case; also, it is not unreasonable to assume that further uses will be found for these by-products as they become available in commercial quantities. In any case the demand for fuel oil for steam-raising purposes and for use in internal-combustion engines increases yearly, and it has been shown that the primary tar oils produced by low-temperature distillation can conveniently be treated to meet this ever-present demand.

Mr. Dransfield's comments on the lay-out of the plant are doubtless based on the impression given by the photographs of the circular retort at Dunston. As mentioned in the paper, this design is being superseded by a retort of rectangular construction, with the result that a very much neater and cheaper lay-out will be possible, as was shown by the lantern slide of the model of the 160-ton-per-day retort working in conjunction with a pulverized-fuel boiler. The reason why pulverized-fuel firing has been adopted in connection with the new retort at Dunston is that, having already demonstrated the suitability of semi-coke for stoker firing, it has been thought advisable also to demonstrate its suitability as a pulverized fuel. No difficulties have been experienced in burning semi-coke from the older retorts on chain-grate stokers, and no difficulty is anticipated either in pulverizing the semi-coke or in maintaining efficient combustion in the furnace of the pulverized-fuel boiler. Regarding the coal in the

Nottingham district, unless the moisture content is altogether abnormal, which we understand is not the case, the preheater will be capable of drying the coal to a sufficient extent to permit of its being treated satisfactorily in the retort. In cases where an exceptional amount of moisture is present it may be necessary to increase either the size of the preheater or the temperature of the preheating gases. The question of whether any coal would be worth while treating is mainly dependent on the yield of oils obtainable under low-temperature distillation conditions. If the ash content of the coal is not too high to make it unsuitable as a boiler fuel when fired in the raw state, it may be assumed that the coke produced will be at least equally suitable as a boiler fuel.

In answer to Mr. Brearley's remarks, the Babcock process is well adapted to the production of semi-coke for domestic purposes. Tests made in stoves and open fire-places have proved that, provided the semi-coke is made from reasonably clean coal, the fuel gives excellent results, as it is easy to ignite and burns freely. It is very well suited for use in stoves and it is possible to maintain a more steady rate of combustion than when high-temperature coke is used. For this purpose it is, in fact, an excellent anthracite substitute. Dunston semi-coke has now been used for some time in open fire-places at Babcock House, and owing to its cleanliness is preferred to coal. We agree that the value of this fuel is greater for domestic than for industrial purposes, but that fact should not absolve us from endeavouring to get the best out of the coal used for industrial purposes. It should be quite possible to install low-temperature distillation plant at large coal-consuming centres such as electrical generating stations, and to arrange matters so that the larger size of semi-coke produced by the retort would be sold as a domestic fuel and the smaller size used either on chain grates or in pulverized form for steam-generating purposes. The process is quite well suited for this dual purpose. It is agreed that the combustion of coal in modern power stations is now carried out under conditions which reduce the emission of smoke to a minimum, but in a large number of coal-consuming undertakings this is not the case, and in such instances the use of semi-coke would undoubtedly be of considerable benefit to the health of the community.

In reply to Mr. Wilkinson, the cracking of the primary tars produced by low-temperature distillation has not yet been undertaken on a commercial scale, but tests have been made which show that these tar oils are amenable to treatment by recognized cracking processes and will produce from 30 to 40 per cent of high-grade motor spirit possessing excellent anti-knocking properties.

In reply to Mr. Wyness, the process has been designed to deal with coal of the grading normally used in power stations; an example of this grading is given on page 220 of the paper. In actual practice it is preferred to treat coals having less than 20 per cent of fines below a $\frac{1}{8}$-in. sieve. As regards the input and output of the plant, it is preferable from an economic point of view to work the retorts at the full rate of through-put for which they are designed, although it is quite possible to reduce this rate if required to meet the load requirements of the boiler plant.

The points raised by Mr. Woods have already been referred to in the preceding part of the discussion.

NAVAL WIRELESS TELEGRAPH COMMUNICATIONS.

By G. SHEARING, B.Sc., and Captain J. W. S. DORLING, R.N., Members.

(*Paper first received 5th July, and in final form 14th October,* 1929; *read before the* WIRELESS SECTION *4th December, and before the* HAMPSHIRE SUB-CENTRE *19th December,* 1929.)

SUMMARY.

The paper gives a short account of the development of wireless telegraph apparatus for naval purposes. The historical development is referred to, the wireless telegraph lines required for naval ships are outlined, and the essential requirements and chief features of some of the apparatus used under sea-going conditions are briefly described. The organization for giving effect to the policy of H.M. Board of Admiralty is also indicated.

Part (1). HISTORICAL.

The first experiments in wireless telegraphy in the Navy were commenced by Captain H. B. Jackson, R.N. (now Admiral of the Fleet Sir Henry Jackson) in H.M.S. "Defiance" in 1896. Trials were carried out in 1897 between "Defiance" and the gunboat H.M.S. "Scourge," when ranges up to 3½ miles were obtained. The transmitting apparatus consisted of a Hertzian oscillator energized by an induction coil worked either from the electric light mains through a resistance or from a 12-volt battery. The arrangement is shown in Fig. 1. A diagram of the receiving circuit is shown in Fig. 2, the detector being of the coherer type, a glass or ivory tube containing two metal plugs being employed. It will be seen from the diagram that arrangements were made for the automatic recording of signals.

As a result of these early experiments, attempts were made to develop greater power with a view to getting longer ranges, and in 1898 this development work was in hand, but trouble was experienced owing to the failure of the induction-coil insulation under damp conditions. This difficulty was eventually overcome by coating the coil with paraffin wax, and, in 1899, sets were fitted in H.M. Ships "Europa," "Juno" and "Alexandra," Mr. G. Marconi (now Marchese Marconi) being in charge of the trials, which were carried out during the peace manœuvres. Effective ranges of 50 miles were obtained during these trials. The collaboration between scientist and naval officer, started at this early stage, persists to the present day with equally fruitful results.

In 1900 further progress was made and by the end of the year 43 ships and 8 shore stations either had been, or were being, fitted with wireless telegraph apparatus. Thirty-two of the sets employed were supplied by the Marconi Co., the remainder being constructed in H.M.S. "Vernon" and H.M.S. "Defiance" to Captain Jackson's specifications. The speed of signalling was about 10 words per minute and reception was automatic.

During 1903, Muirhead's automatic transmitting apparatus was installed for trial. Only two waves were in use at this time, these being known as "A" tune and "B" tune, "A" tune being of 395 ft. and "B" of 1 150 ft. A variable-wave set known as "C" tune was developed at a later date. The magnetic detector was tried and introduced at this period.

In 1905 a naval wireless telegraph establishment was organized in "Vernon" and work was commenced on an experimental 5-kW set for erection at Horsea Island in Portsmouth Harbour. In this year the well-known rejector circuit for reception was introduced by Mr. H. A. Madge, who had recently been appointed as civilian wireless expert in "Vernon."

FIG. 1.

At the end of 1905, naval interest in wireless telegraphy was somewhat on the wane owing to the very large number of failures which had occurred during trials at sea. At the beginning of 1906, however, a series of competitive exercises was carried out in the various fleets, with more satisfactory results. Up to this time, the development of wireless telegraphy had been under the control of the Torpedo Branch of the Navy, but signalmen had been used for operational purposes.

In 1906 it was decided to commence a new branch, the Wireless Telegraph Branch, in which men could specialize. This had very marked beneficial results, as would be expected since the candidates for the new branch were all compelled to undergo a special course of training in wireless telegraphy. Operators rapidly became more efficient and the number of failures during manœuvres consequently decreased.

During 1906, experiments were carried out on a number of new wavelengths. Towards the end of the year, range trials were carried out between "Vernon" at Portsmouth and H.M.S. "Furious" on passage to the Mediterranean. Ranges of 600 miles were obtained regularly by day and up to 1 200 miles by night. The wavelength known as "R" tune, 2 500 ft., was found to be the most satisfactory. A long wave of 7 000 ft. was not found satisfactory. During this year, with more operators available, telephone reception became the normal procedure and the silent cabinet for reception was introduced in ships.

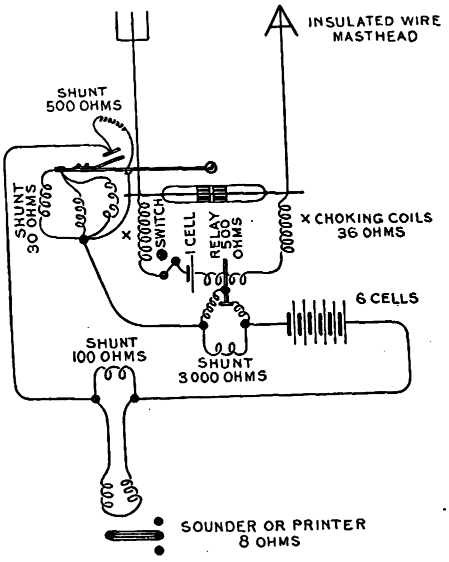

FIG. 2.

In 1907 the service Mark II set, later known as Type 1 spark, of the order of 12-kW H.T. output, was introduced for heavy ships, and, in 1908, experiments were commenced with the Poulsen arc in "Vernon" and "Furious." Preliminary experiments with wireless telephony and various forms of crystal and electrolytic detectors were also commenced in this year.

In 1909 the crystal detector was first used. High-power shore sets employing spark telegraphy were put into operation at Horsea, Cleethorpes and Gibraltar, and medium-power sets at Pembroke, Aberdeen and Ipswich. In 1910, a quenched-spark set was built for the naval airship. In this year also a wireless telegraphy course for officers qualifying for the Signal rank of Lieutenant (S) was approved.

During the years 1911–1912 a very considerable amount of experimental work was done, using the Poulsen arc, but there was no standardization of the apparatus at this period. The question of the development of methods of accurately measuring wavelengths also received considerable attention. During these years, also, the development of spark telegraphy sets continued and by 1913 the following were the main ship sets then in use:—

Type 1 (old Mark II main-power set).
Type 2 (old Mark I original low-power set).
Type 3, battleship auxiliary set.
Type 4, destroyer set.
Types 5 and 6, portable and harbour defence sets.
Type 9, cruiser auxiliary set.
Type 10, submarine sets.

Of these sets, Type 1 utilized a d.c. power supply of 20 kW, the remainder 3 kW or less.

During 1913 a 100-kW Poulsen arc was installed at Horsea Island, and three 440-ft. wooden lattice masts were erected, this work being carried out by Mr. C. F. Elwell. Also during this year the use of heterodyne reception for continuous waves was commenced.

During 1914, immediately prior to the commencement of the War, experiments were in hand on valve reception and arrangements were being made for complete arc sets to be supplied to ships at sea. The commencement of the War gave a great impetus to the development of wireless telegraphy, and the development of the thermionic valve is mainly associated with the war period from 1914 to 1919, first as a method of reception and later as a transmitter. In 1917 the wireless telegraphy established in "Vernon" was transferred ashore to H.M. Signal School, Portsmouth.

Whilst spark and arc systems of wireless telegraphy were mainly employed by ships at sea during the war period, the experimental development of the valve during the same time indicated that there was a probability that both these systems would ultimately be superseded by the thermionic valve system. In January, 1919, aerial currents of 50 amperes were obtained using a shore station valve transmitter.

The post-war developments which have occurred since 1919 have confirmed this view, and at the present time, except for special emergency purposes, spark transmitters are becoming obsolete and arc transmitters have been almost entirely replaced by valve transmitters in all types of ships. At the conclusion of the War, sets employing valves for power transmissions utilized valves of the order of 400 watts anode rating, but since this period the development of power valves has been rapid, until now single valves are in use with sets at sea which are capable of dissipating 8–10 kW at their anodes under oscillatory conditions.

The high-power sets developed up to 1923 were long-wave transmitters for long-range working, but during this year long-range experiments at sea in connection with the higher frequencies above 3 000 kilocycles per sec. (100 m) were commenced. During cruises in 1924 and 1925 of H.M.S. "Yarmouth" to the Canary Isles and to the Mediterranean, it was found possible to maintain short-wave communication with ships at Portsmouth during certain periods of the day, and in 1925 these experiments were continued with good results at greater distances to the Far East. The world cruise of H.M.S. "Renown" during January to June 1927, provided another opportunity for testing the capabilities of short-wave working on long ranges, and except for three days in a period of six months it was found possible to maintain communication during a part of each day of the cruise between Whitehall and "Renown," Whitehall controlling a short-wave transmitter at Horsea Island.

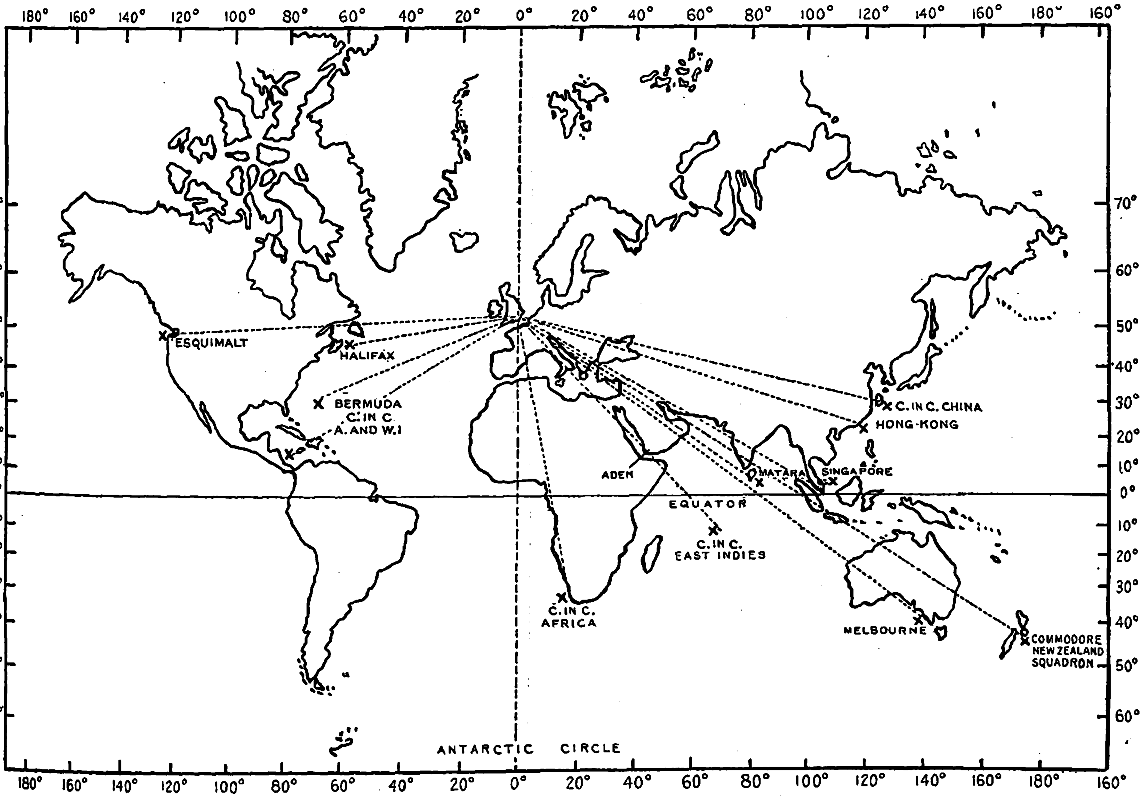

FIG. 3.

Regular service routines employing short waves between England and naval ships and shore stations overseas have now been in operation since 1926.

Apart from the direct application of wireless telegraphy to communications, the apparatus developed by H.M. Signal School for distant control, by the use of wireless signals, of target ships, such as H.M.S. "Agamemnon" and H.M.S. "Centurion," is well known and has been referred to in the Press.

Part (2). REQUIREMENTS TO BE FILLED BY A NAVAL WIRELESS TELEGRAPH SYSTEM.

It is a truism that trade follows the flag. The reverse that wherever trade flows there must the flag be also, is equally true.

The trade of this country is world-wide, and hence British men-of-war are to be found in all parts of the world. These ships are divided up into squadrons and are normally stationed in certain areas, for example China, East Indies, Africa, America and West Indies. Each squadron is under the orders of its Naval Commander-in-Chief.

A system of communication, to be effective, must link up the ships of these far-flung squadrons with their own Commander-in-Chief and with the Admiralty. The backbone of the system consists of a series of naval shore wireless stations situated in various British possessions throughout the world and in most cases forming a continuous chain of communication as indicated in Fig. 3 (Horsea and Mediterranean stations are not shown).

NAVAL SHORE WIRELESS STATIONS.

In the United Kingdom there are therefore wireless stations designed to communicate with ships in adjacent waters, and others for really long-distance communication with the stations abroad. Each naval area or station abroad has, depending on its size and position, one or more wireless stations, which act as terminal points for the traffic to and from the Admiralty and other commands, and as distributing and collecting centres for ships in the vicinity. Where commercial wireless stations are not available the naval stations are used also for communicating with merchantmen.

The wireless telegraph apparatus of these shore stations has therefore to be capable of communication with:—

(*a*) The Admiralty, either direct or through links.
(*b*) The Commander-in-Chief of the station and the ships on his station.
(*c*) Any merchant ships in the area.
(*d*) Adjacent naval commands.

To fulfil these requirements a medium-power long-wave valve transmitter of about 25-kW H.T. input is usually fitted for local working within a radius of, say, 1 500 to 2 000 miles. For the longer distances short-wave transmitters of various types are used. These range from 2- to 10-kW H.T. input. Recently it has been the practice to put all the receiving apparatus in a separate building at some distance from the transmitters.

Arrangements are made whenever possible for the wireless stations to be linked up with the cable and land-line system.

Cruisers and Other Ships on Foreign Stations.

These ships must be able to communicate with:—

(*a*) The Commander-in-Chief of their station and other ships on the station.
(*b*) The shore wireless station in the area.
(*c*) Adjacent commands.
(*d*) Merchant ships and aircraft in their vicinity.

The advent of the short-wave system has made it possible for ships in any part of the world to communicate direct with each other and with the Admiralty at certain times of the day. This facility is made use of to supplement the normal lines of communication and to avoid delays to especially important messages.

To fulfil the requirements stated above, the wireless telegraph equipment in H.M. ships of cruiser class and above has the following characteristics:—

(1) Range (long wave)—1 000–2 000 miles.
(2) Power (long wave)—12-kW H.T. input to transmitter.
(3) Power (short wave)—8-kW H.T. input.
(4) Valve transmitters are used in all cases.
(5) Receiving apparatus (long- and short-wave). Two or three sets are fitted.
(6) Direction-finding apparatus on the Bellini-Tosi system is fitted in most cruisers.
(7) Fire-control wireless sets are fitted for use when cruisers are concentrated in squadrons.

Apart from its actual technical performance, the apparatus must have certain very definite characteristics to fit it for use in a ship at sea. For example, it must be robust, simple to handle, reliable under all climatic conditions, proof against vibration and the shocks of gunfire, and capable of being maintained in full efficiency for months at a time by the ship's wireless staff.

The Main Fleet.

So far we have only considered the shore wireless stations and the cruising ships on foreign stations. Behind the cruisers and the ultimate source from which they obtain their liberty of action is the main battle fleet—the Grand Fleet of the Great War.

A self-contained battle fleet consists of battleships and battle cruisers which provide the main fighting power, together with cruisers for scouting, aircraft carriers, destroyers and submarines.

The whole force is under the command of its Commander-in-Chief, who must be able to transmit his orders to any unit of the force. The scouting units of the fleet must be able to transmit the information they obtain to the Commander-in-Chief and the other senior officers of the fleet. The Commander-in-Chief must also be in touch with the Admiralty and other authorities.

All these lines of communication should be able to work simultaneously without interference. This is usually done by multiple reception in the flagship, all transmissions being made by wireless guardships specially allocated for each wave. The apparatus used for these purposes is similar to that fitted in cruisers, already outlined.

Short-distance apparatus is also fitted in special offices in the battleships and cruisers to permit of inter-communication within the fleet without interfering with the long-distance lines. This short-distance apparatus is used for manœuvring the battle fleet and also provides an essential link between the wireless guardships and the flagship.

The striking feature of a fleet action is the speed at which everything happens. The two fleets may be approaching one another at 40 to 50 miles an hour, and even with aircraft reconnaissance the time between first sighting the enemy and joining action may be only an hour or two. During this limited time the scouts of the fleet have to observe that part of the enemy fleet which may be in sight, determine their position, composition, course and speed, and then signal this information to the Commander-in-Chief. From all these reports he has to determine what the enemy as a whole are doing and then manœuvre his force into the best position. The volume of signalling during this critical hour or so is very great, especially in the fleet flagship, and special means are necessary to ensure that no signal is delayed. The wireless apparatus is designed for the rapid handling of messages and so that the guardships can readily control the traffic on their particular wave-lengths. In all ships the messages are received and transmitted, not in the wireless offices between decks, but in a remote-control office near the Admiral's or Captain's bridge, thus reducing to a minimum the intermediate stages between the issue of an order or report and its receipt by the person for whom it is intended. Pneumatic tube and buzzer systems are fitted for the rapid transmission of messages in case of a breakdown of the remote-control system.

The direction-finding sets fitted in some ships often prove their value during this stage of the action. Direction-finding bearings may be obtained of the enemy, or, should, for example, some of the scouting vessels or aircraft be uncertain of their positions relative to the battle fleet, a wireless bearing may be a useful check.

Wireless communication is also largely used after the action has started. Reports of the movements of the enemy forces continue to be made, and the fleet is manœuvred by a combination of wireless and flag signalling

All ships, down to destroyers, also use special low-power sets for fire control. The essential feature of this line of communication is that it should be free from interference from any other line and absolutely reliable even under action conditions.

For obvious reasons it is not possible to elaborate the above outline, but it will be sufficient to show that the requirements of a naval wireless system are many and varied, and that the overall efficiency of the Navy must depend largely on the efficiency of its wireless communications.

Part (3). Offices and Apparatus.

Typical Office Arrangements.—The initial lay-out of a modern warship involves an immense amount of preliminary work and trouble in the process of subdividing the available space for the various requirements. The fact that the ship is to be capable of fighting in action is a primary factor, and when provision has been made for the essential armament, propulsion machinery and living quarters for the crew, the space available for any other given requirement is very limited.

The ideal communication requirements are, of course, known, and a preliminary estimate of the space necessary is usually worked out in advance by the technical staff for the information of the Board of Admiralty. The actual space available is almost invariably found to be less than this estimate and it then becomes a matter of compromise as regards how far the ideal requirements may be met in the space which can be allocated. In this manner the wireless telegraph office is evolved of definite dimensions into which the main portion of the apparatus, apart from aerials, is to be placed. The general arrangements for the wireless telegraph offices and aerial systems of a battleship are indicated in the simplified diagram, Fig. 4.

MAIN W/T OFFICE C.R.R. & CODING OFFICE
AUXILIARY SETS OFFICE

Fig. 4.

The main and auxiliary offices for heavy ships are situated below the main armoured deck, and the space has to include the following:—

(*a*) A silent cabinet for the accommodation of the receiving gear from which small trunks or cables go to the various receiving aerials.

(*b*) A cage protected by safety gate switches in which are contained the high-tension power supply and auxiliary apparatus for the transmitters. These have to supply oscillatory power to the aerial by means of a conductor fitted in a trunk which goes to the deck insulator to which the aerial system is connected.

(*c*) Low-tension power control apparatus for the wireless-telegraph motor-generators.

(*d*) Suitable gangways for ready access to all controls and for visual inspection of instruments.

(*e*) Coding office.

Fig. 5.—Typical lay-out of wireless telegraph offices in heavy ships.

Primary Requirements.—The main conditions to which the wireless telegraph apparatus should conform are:—

(*a*) Space and weight limitations.
(*b*) Reliability of operation.
(*c*) Mechanical strength to resist shocks arising from gunfire and sea-going conditions.
(*d*) Ability to withstand extremes of temperature and weather.
(*e*) Efficient operation in offices below the main armoured deck, connected to the aerials via trunks or conductors of length which may exceed 100 ft.
(*f*) Minimum possible time of starting up for transmissions, with listening-through arrangements.
(*g*) Safety for operators. Controls readily accessible for quick operation.
(*h*) Rapid tuning arrangements covering a wide band of waves.
(*k*) Simple and easy to operate.

Design and Development.—The problem of designing oscillatory apparatus to fit into a given space which invariably is very much less than that available for the same power in shore stations imposes limitations on the technical design. The circuits and adjustments for wave-change have to be reduced to the minimum possible, the arrangements for replacement of gear have to be easy and rapid and the indicating instruments have to be capable of being viewed from widely varying positions.

Fig. 6.—Lay-out of wireless telegraph office for light cruisers.

The procedure usually adopted is to develop experimentally the apparatus first in a wooden model of the office space. From this the proposals and specifications for fitting the set in ships are prepared. Lay-outs for typical wireless telegraph offices of various sets for battleships, cruisers and destroyers are shown in the plans, Figs. 5, 6 and 7.

Installation and Trials.—The installation of the sets is carried out by the contractor or dockyard under the supervision of H.M. Signal School, Portsmouth, the completion of the wiring and final tuning of the high-frequency apparatus being carried out by the co-operation of the Signal School and the ship's staff. This installation work includes the following:—

(*a*) Fitting lined receiving rooms (silent cabinets).
(*b*) Fitting safety screen and all apparatus components.
(*c*) Fixing ventilation fans, air supply and exhaust trunks.
(*d*) Construction of aerial trunk, deck insulators and aerial conductor system.
(*e*) Fixing of all moving machinery, which is fitted outside the office.
(*f*) Wiring work as specified, covering low-tension lead-cased or bare high-tension wiring.

Upon the completion of the installation, the ship's staff has to carry out the following duties:—

(i) Test all the running machinery.
(ii) Complete the high-tension and high-frequency wiring for the transmitters and receivers not shown in the specification.

The sets are then ready for tuning and external communication trials, which are carried out by Signal School Officers in conjunction with the ship's staff.

Apparatus.

(A.) *Power Supplies for Main Wireless Telegraph Transmitters.*—The power supply for both thermionic valve or spark wireless telegraph transmitters is mainly high-tension low-frequency alternating current, and the earlier post-war development of valve transmitting sets was facilitated by the fact that existing power plant which was installed initially for spark transmitters could be used also for valve transmitters. The frequency value for the alternators has been determined mainly by

the note frequency which can be read easily through other wireless telegraph interference and is not tiring to the operator when listened to for long, continued periods. For spark transmitters the frequency adopted was 350 cycles per sec., giving a note frequency of 700, but for the valve transmitters this has been changed to 500 and 1 000 cycles respectively.

The power supply for the motor-generators is taken from d.c. busbars on power boards in the wireless office supplied from the ring mains of the ship. This supply is at either 220 or 100 volts, depending on the ship. The ring-main power supply is in duplicate and these supplies are via branch circuit-breakers fitted in separate watertight compartments outside the wireless telegraph office which are controlled by "on" and "off" pushes from inside the office. The machines are usually installed below the water line of the ship, with their axes arranged fore and aft. It is usual to mount one pair of machines, e.g. main and filament motor-alternators, in one watertight compartment separate from the other pair. The earlier machines were of three-bearing type, but these have now been superseded by four-bearing machines, the motor and alternator being separate machines with flanged coupling, due to overheating of bearings with the earlier type and the greater ease of passing the four-bearing machines, when separated, through the hatchways.

Duplication of the machines and power panels is adopted, each motor-generator being installed complete with its own d.c. and a.c. control gear. In addition, arrangements are also made whereby either machine can be operated from either startor. For certain cases automatic control gear is installed to give a constant value of generated voltage.

(Low-power panel not shown.)

The power panels themselves are of metal framework structure and follow general electrical engineering practice for marine purposes. Each of the panels is contained in an angle-iron frame so arranged that any of the individual units can be readily removed.

Subdivision is carried to a greater degree than otherwise would be the case, to enable each part to pass through the hatches.

The power supply is so arranged that both machines may be running simultaneously, but if one is on load then the other must be running light. The power panels are comprised in four main parts which subdivide into two parts. These parts serve the following functions:—

(i) D.C. supply and a.c. output board for the filament motor-alternators.

(ii) D.C. supply board for main alternators, with busbars for supplying No. 1 board.
(iii) Distribution board for lighting and all auxiliary circuits, including operating and control circuits, fans and motors charging battery circuits.
(iv) A.C. distribution board for main alternator.

A schematic diagram showing the general arrangements and functions of these parts is shown in Fig. 8.

The earlier hand-starting has been replaced by autostartor controls and these have proved much more satisfactory than the hand startor. Tests have shown that the auto-startors fitted do not throw off under the normal vibrations of the ship or shock from gunfire. As typical circuit illustrations for the power boards, wiring diagrams for the d.c. and a.c. supply boards for the main motor-alternator are shown in Figs. 9 and 10. With regard to the d.c. board, duplicate supplies are taken from the busbars through pairs of circuit breakers. The positive supply leads go from each circuit breaker to one of the two startors for the motor-alternators. The negative lead goes to an 8-pole, 2-way change-over switch which serves the dual function of d.c. change-over for alternators and for startors, enabling either startor to be used with either motor.

The a.c. board supplies the primary of the main h.t. transformer. This supply is via a safety relay switch and magnetic key. Two magnetic keys are fitted and switching arrangements provided whereby either key can be brought into use for signalling with either alternator. The magnetic key is operated for signalling by solenoid control from the morse key.

The distribution boards also include indicating lamps and safety devices as follows:—

(*a*) Indicating lamps for main and filament d.c. motors.
(*b*) Indicating lamps for main alternators.

(B.) *Design of Valve Transmitters for Long and Short Waves.*—It is not intended here to discuss the types of wireless telegraph circuits which are employed. The earlier post-war valve transmitters * were either directly connected to the aerial circuits or coupled via an intermediate or primary oscillatory circuit, these transmitters being used on what are usually known as long or medium waves, i.e. frequencies between 60 and 3 000 kilocycles per sec. (5 000 and 100 m). The later designs employ master-oscillator types of generator circuits, the frequencies in certain cases (for the shorter waves) being stabilized by quartz crystal control. The introduction of short waves has modified the requirements very considerably. Their advantages for long-range working at distances from a few hundred miles up to world-wide ranges during certain portions of the 24 hours of each day are well known, and it has been necessary to arrange for the fitting of attachments to existing longer-wave sets capable of transmitting on a band of waves covering 4 300 to 21 500 kilocycles per sec. (70 to 14 m).

---

* See G. Shearing: "Naval Wireless Telegraph Transmitters Employing Rectified Alternating Current," *Journal I.E.E.*, 1925, vol. 63, p. 309.

The general arrangement of the oscillatory circuits for one of the earlier main valve long-wave transmitters with short-wave attachment is indicated in Fig. 11. The rectifying and oscillatory circuits, with the exception of the aerial coils, are arranged in panels of light steel or aluminium alloy framework with the front and outer ends protected by expanded-metal screens. These panels are supplied with the internal wiring completed as far as practicable. The arrangement of typical rectifying and long-wave transmitting panels is shown in Figs. 12 and 13.

(C). *Operating Controls for Valve Transmitters.*—For a valve transmitter as shown in Fig. 11, the following d.c. circuits are provided:—

(i) Signalling and remote-control circuits for operating all the switches working in unison with the morse key, e.g. magnetic key for main power to valve set, anode key for isolating the valve anode circuit from the aerial circuit, operating and cabinet switches which are closed for earthing the receivers during marking and opened for listening-through during spacing. The circuits of the remote-control bobbin and repeater to the bridge are also included. The morse key is fitted with a bobbin attachment for operation from the bridge and other remote positions.

(ii) Blowers for valve cooling and main safety circuits. The main power-supply relay is in series with the blower circuit when the gate of the cage is closed, so that it cannot be "made" until one of the blowers is switched on.

A simplified diagram of the valve filament and rectifier switch circuits is given in Fig. 14. The double-contact switch ensures that the rectifier switch contact "a" (see Fig. 12) makes before and breaks after the filament switch contact " c ", which is in the filament alternator supply lead to the primaries of all filament transformers (see Fig. 13). Thus no filament current is flowing when the rectifier switch is broken. If this were not done the contacts might fuse and prevent the switch from short-circuiting the smoothing condenser when the set is shut down after a transmission.

In addition, it will be seen in Fig. 14 that the contacts of the overload and blower relays are placed across the filament-switch magnetizing bobbin, so that unless they are open the filament switch is also open and the valves are switched off. The overload relay contacts close and switch off the valve filaments if for any reason whatever the valves carry excessive current. Similarly, the

Signalling control of the main sets is usually provided for by alternative morse keys, one of which is installed in the central receiving room adjacent to the operator, and the other on the d.c. distribution panel adjacent to the set for testing purposes. A schematic diagram of this circuit is given in Fig. 15, in which are shown:—

(*a*) The keying circuits for operating the magnetic key used for signalling.

(*b*) Circuits for closing the anode key in the transmitter circuit, the operating switch in the aerial earth lead and the cabinet switches for earthing receivers during marking.

(*c*) The bobbin attachment for the morse key when the set is operated from the remote-control positions.

Fig. 16 illustrates the safety circuits, which are supplied from a 2-pole switch from the distribution panel. From this it will be seen that the main power relay is opened whenever the safety gates are opened. As a protection against signalling when a man is aloft, an indicator plate with the words " man aloft " is hinged to the power board in such a manner that when bolted down it fouls the switch handles of the 2-pole switch and so prevents it from being closed.

The alarm circuit for other wireless telegraph offices utilizes a separate d.c. 20-volt supply. In each office is provided a buzzer and lamp. With the closing of the main safety gates the buzzer sounds and the lamp glows. With the earthing of the office aerial the buzzer ceases to sound but the lamp continues to glow so long as the main set is in operation. A diagram of the operator's control board installed in the central receiving room is shown in Fig. 17. The method of arranging the panel d.c. circuits which are connected to the control board is shown in Fig. 18. Each separate panel can be transported with its control circuits completely wired, and links complete the circuits between panels.

(D.) *Valve Transmitters having High Constancy of Frequency.*—The more recent designs of combined long-wave and short-wave transmitters employ master oscillator control for both the long-wave and short-wave circuits. One of these circuit arrangements for a ship transmitter is shown in Fig. 19, in which the control stages are designed for operation on either long or short waves, and the main stage for short-wave operation comprises a high-frequency double-acting system of two valves which are neutralized to avoid retroaction. For long-wave working the valves are used in parallel. Signalling is obtained by grid-potential control. The general arrangements of auxiliary circuits are similar to those described in detail above for an earlier design. Switching arrangements are provided whereby the change from long-wave to short-wave working can be effected.

For shore station short-wave transmitters used for point-to-point working, quartz-crystal controlled transmitters are employed for frequencies of the order of 7 500 to 10 000 kilocycles per sec. (40 to 30 m). In certain cases, frequency-doubler circuits are employed for transmissions on the corresponding band of 15 000 to 20 000 kilocycles per sec. (20 to 15 m), so that one crystal controls transmissions on the two waves. A general diagrammatic circuit of such a transmitter is shown in Fig. 20, in which the amplifier circuits are of high-frequency double-acting design, the third harmonic of the crystal frequency being selected and amplified. Automatic signalling is provided for by grid-potential control of one of the lower power stages, using a Creed relay as indicated in the diagram. Fig. 21 shows circuit arrangements for doubling the frequency, i.e. to the sixth harmonic of the crystal frequency.

In the case of all naval ship transmitters, the circuit design is such that no spacing wave is transmitted and arrangements are provided for listening-through.

(E.) *Assembly of Transmitter Components.*—The main requirements to which the wireless telegraph apparatus should conform have already been enumerated on page 243, from which it will be seen that the assembly and design of the components are a compromise between electrical and mechanical requirements. It is especially important to ensure that the relatively weaker links in the apparatus must all be easy of access for removal for repair and replacement. In assembling the components the distribution of the electric and magnetic fields has to be borne in mind, and undesirable magnetic and electrostatic coupling between coils must be reduced to a minimum. Any long metal parts near high-voltage coils are so mounted that their axes lie as nearly as possible in an equipotential plane.

(F.) *Panel Frameworks.*—The shock of gunfire causes the decks and bulkheads of the wireless telegraph offices in some ships to whip by as much as ½ inch. A framework must therefore be bolted either to the deck or to a bulkhead, but not to both. Fixing to the deck is the best solution. Heavy parts such as transformers and oil-filled condensers are, for this reason, fixed to the framework base to minimize bending-moment stresses due to shock. The question of angle iron, non-ferrous metal or wooden frames for the panels is determined by the space available. If the space is very cramped, voltage considerations may compel the use of wood; if more space is available, then angle aluminium alloys have the advantage of lightness; also, being non-magnetic and of low ohmic resistance, they do not cause appreciable losses. Angle iron has strength but it must be lined with thin copper to reduce its losses where parts cross an intense high-frequency magnetic field from a coil.

(G.) *Transmitter Oscillatory Coils.*—The oscillatory coils used may be very briefly dealt with under the headings of coils used for (i) long-wave, and (ii) short-wave transmitters.

(i) *Coils for long-wave transmitters.*—The materials mainly employed for insulation are ebonite, paxolin, porcelain and pyrex glass. The trend of later design has been to build American whitewood frameworks to support combs of ebonite which carry the coil windings. Porcelain parts have also been used for the combs, these being made from plastic clay which is vitrified by firing, but they were found not to lend themselves to accurate manufacture as regards dimensions. Those made by the dust process have the disadvantage that they are non-homogeneous and are porous before glazing. Paxolin and similar products are only used for parts requiring mechanical strength and not subjected to very high voltages at high frequencies. As regards American whitewood, whilst this is an excellent insulator when kept dry, it is not so satisfactory when subjected to the humid atmosphere in ships. The moisture absorbed by the surface of the wood increases its surface permittivity to such an extent as to cause brushing under the very high voltage gradients which exist for the coil designs due to space limitations. Treating the surface of the wood

with a heavy coat of varnish largely destroys its high insulating properties, and the use of a very thin layer of varnish has been found to be not entirely satisfactory. As regards dimensions, a ratio of 3 : 1 in diameter to length gives the most efficient design of coil so far as copper losses and the length of wire for a given inductance are concerned. To obtain the required number of tapping points over a large range of frequency and to utilize the space within the framework to the best advantage, it is, however, usually necessary to reduce this ratio to 1: 1. In ship sets the long-wave coils are nearly always wound multi-layer because of space limitations. Stranded wire, each strand being insulated, is largely used and the windings are carried in slots. These slots are so designed that the voltage stress across a tooth does not exceed 5 000 volts per inch under the worst conditions. It is necessary to guard against the assumption that the greater the number of strands of the standard size (No. 38 S.W.G.) used in the wire, the less will be the resistance of the coil. For a given conductor there is a best spacing of the strands in the conductor and a best spacing of the conductors forming the coil. It is also desirable to keep the number of terminals down to a minimum. If a coil of N turns be tapped to form sections each having $\sqrt{N}$ turns, and if the last section is tapped at every turn, then the coil inductance can be tapped in steps of one turn throughout and the number of tapping points will be a minimum.

(ii) *Short-wave coils.*—For the larger ship sets these are wound with copper tube which carries a tapping clip for adjustment of wavelength. These coils are almost self-supporting but the end turns and a middle turn are usually clamped to porcelain insulators mounted on a wooden base, and in all designs the maximum permissible rigidity is necessary to secure constancy of wavelength. The electrical considerations tend to weaken the mechanical design, e.g. the turns have to be spaced sufficiently far apart to prevent the tapping clip from short-circuiting to the adjacent turns, and the coil has to be long compared with its diameter to enable single-turn tappings to be made having sufficiently fine adjustment of inductance in addition to the insulated clamping supports which are fitted to secure rigidity. The coils are also cooled by air blast to reduce the variation of frequency which otherwise occurs with change of temperature.

(H.) *Transmitting Condensers.*—The development of fixed condensers for specified wireless telegraph transmitting requirements is left to the makers of such apparatus. The usual type consists of copper-foil plates and ruby-mica dielectrics built up in sections connected in series or series-parallel as necessary to meet the specified conditions. Great care is taken to exclude any air bubbles between the plates and dielectric. The best procedure for assembly is to arrange for the sections to be placed in a vacuum in order to withdraw any air present within the condenser unit, and afterwards to dip them in paraffin wax for sealing. The procedure of placing the sections simply in boiling paraffin wax to drive out the air by heat is not satisfactory, for a proportion of the air may become sealed in spaces between the plates and dielectric at less than atmospheric pressure, and ionization losses may then occur.

The long-wave transmitting condensers usually have their units assembled in metal cases which are filled with either oil or wax and to which one of the condenser terminals is connected. The type of design which is favoured is that in which the case is suitably insulated from earth by porcelain pillars or blocks, by reason of the saving in space and cost for the container. It is of special importance to give the manufacturers full information as to the type of load and working conditions. The losses in a condenser are less when it is used in a spark or interrupted-continuous-wave circuit than for the case when the same circuit is used for continuous waves and passing the same effective current. The peak voltage values for the former are, however, much higher. The power factor of a good mica condenser is of the order of 0·2 of 1 per cent, but if the condenser is poorly constructed this power factor may easily increase to give double the power loss.

NT4A VALVE
NT31 VALVE
NEUTRALIZING CONDENSERS

FIG. 21.—Frequency-doubling circuits for short-wave transmitter.

In connection with the losses in a condenser, the arrangement of the condenser plates is of great importance, for if the sections are so arranged that the bottom plates are connected to a low-potential terminal and the top plates to the high-tension terminal, the high potential gradient around the edges of the top plate may then cause heavy losses in the top clamping plate of insulation. Cases have been experienced where ebonite clamping plates have melted locally, adjacent to the edge of the top plate. Designs in which the condenser is arranged in two sets of units connected in parallel so that the h.t. plates face one another at the centre are much better in this respect; also, metal clamping plates may then be used. In certain cases fixed condensers are employed in short-wave transmitting circuits and it is then essential to keep the current path through the terminals, leads and condenser elements as short as possible, otherwise the inductance of this path may become serious.

The adjustable tuning condensers used either are oil-filled for long-wave high-voltage transmitters or employ air dielectric for short-wave transmitters. The oil-filled condensers for small transmitting sets are usually more troublesome than the larger units, owing to the fact that any fibres in the oil are drawn between the plates by electrostatic attraction, with a tendency to bridge the plates. The condensers for short-wave transmitters are of low capacity, and to get a reasonable variation it is essential to keep their minimum capacity as small as possible. The chief difficulty experienced with the short-wave condensers is that a small roughness on one plate may start a brush discharge and cause arcing-over at a comparatively low voltage. In the case of transmitting sets employing neutralizing condensers, there is also the difficulty of maintaining the capacity-to-earth ratio of each set of plates constant to secure the symmetry which is essential for satisfactory operation throughout the tuning range.

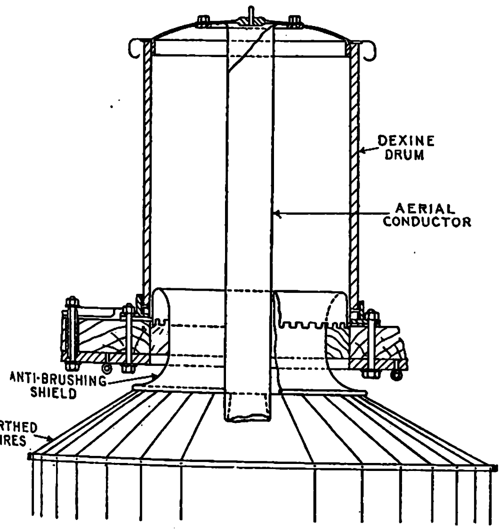

FIG. 22.—Deck insulator.

(J.) *Main Aerial Trunk and Deck Insulators.*—The fact that the main wireless telegraph office is usually situated below the main armoured deck has necessitated the fitting of special trunks whereby the high-frequency energy may be delivered to the main aerial with minimum loss and without danger to personnel. The trunk itself is of steel, and to prevent loss of power due to eddy currents it was formerly usual to fit a cylindrical system of earth wires which were soldered to the copper lining of the deck insulators. These deck insulators were fitted on the upper deck and at the exit for the aerial conductor from the wireless telegraph office. In addition, a similar deck insulator was fitted at intermediate decks if these were armoured or formed part of the watertight sub-division of the ship. More recently the use of the earth wires has been abandoned. In some cases, however, the trunk is copper-lined. One design of deck insulator system is shown in Fig. 22.

The insulating material used in this particular arrangement is dexine, which has the disadvantage that if it becomes encrusted with salt, owing to exposure to spray, a burn-out is liable to occur. If, however, the burn-out is not too deep, so that the charred material can be removed by scraping, and the surfaces are then varnished with shellac, the insulator can be used again. More recently a porcelain bowl-shaped insulator has been used with suitable fittings for securing it to the lower deck casting as shown in Fig. 23. The upper casting and the central cylindrical conductor are at the aerial high-frequency potential, the copper lining being an anti-brushing shield of spun copper fitted through the hole in the deck. The aerial feeder inside the trunk is a copper tube of about 2 in. diameter. For the deck-insulator design of Fig. 22 the joints between the insulating drum and the castings are made by means of a bitumen compound to ensure the arrangement being watertight; dermatine rings are used for the design of Fig. 23. It is important to note that the insulator itself is not of sufficient strength to withstand a considerable pressure in an upright direction, and for this reason the steel trunk itself is designed to be a watertight structure with all doors and manholes into it fitted as watertight doors.

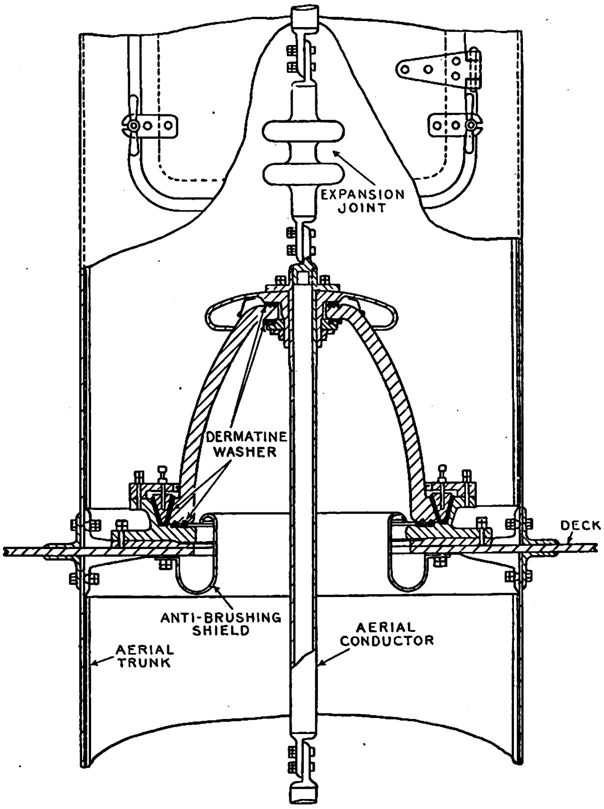

FIG. 23.—Deck insulator.

(K.) *Main Aerial Systems and Insulators.*—Two types of aerials have been employed in main aerial systems, these being either:—

(i) Sausage aerials having two or more legs each comprising 10 wires on circular spreaders at about 1 ft. diameter, or

(ii) Flat roof aerials of about 6–8 single wires in parallel, arranged along yards of 30 to 40 ft. in length.

Experience with these two types indicates that for a given range and capacity there is very little difference in the communication, and the mechanical considerations of handling, rigging and maintaining the aerial in position are the main deciding factors as regards which type of aerial is employed. The chief advantages of the flat roof over the circular-spreader type of aerial are the reduction of strain on the masts for a given aerial sag and windage, the greater ease of handling and the reduction in cost. The wooden yards used for supporting the aerials are painted with an aluminium paint, thereby forming a metal sheath over the wood and preventing charring around the points of metal bolts or screws, which may otherwise be caused by brush discharges from the high-frequency field.

The run of the aerial feeders is of very great importance for efficient working. They must be set well clear of all obstructions and, especially, kept as far as possible from the tops of the funnels to avoid (*a*) reduction of effective height, and (*b*) the losses which otherwise may occur due to the low resistance from ionization of the gases. The upper deck insulator is provided with a spray shield formed by a light sheet-steel screen of about 5 ft. diameter around the deck insulator, and a special outhaul is necessary to ensure that the feeder is well clear of the top edge of the spray shield, unless the adjacent superstructure can provide a suitable attachment. The design of aerial systems for submarines, although they are smaller than those for main aerials of heavy ships, is in some respects more complicated, due to the fact that provision has to be made for raising and lowering the main aerial, which is only employed for surface working, so that it may be taken down and housed prior to diving. The mast is usually of telescopic design. For instantaneous working immediately after surfacing from submerging, a smaller (fixed) aerial is employed.

The strain and rigging insulators at present in use are of porcelain. This material, if properly glazed, has good electrical qualities for high-frequency working, and one of its chief advantages is the ability to withstand sea weather conditions and arcing over its surface for long periods without injury. Its mechanical strength is not so satisfactory. It is especially liable to fracture under mechanical shock, and cases are known where aerial systems have collapsed for this reason. In some cases where the porcelain insulator is cemented by the use of solder into metal end-sockets, failure has occurred due to melting of the cement from the heating of funnel gases, and special designs have been prepared to avoid this danger. In a few cases, also, a curious defect has occurred in some porcelain insulators. If the temperature is a little too high when stoving the glaze during manufacture, very minute bubbles appear in it. If some of these bubbles break and the salt from sea spray lodges in the resultant holes, a very serious reduction in the insulation resistance may be brought about. For this reason there is a tendency to use pyrex glass in place of porcelain. Tests of insulating materials are continuously in hand with a view to obtaining, if possible, a material having both good electrical and mechanical qualities.

The requirements of a good aerial strain insulator may be summarized as follows:—

Electrical.—High surface and volume resistivity. Low dielectric hysteresis loss. Preferably, low permittivity.

Mechanical.—Mechanically strong under tension. Must not be brittle. Surface must not deteriorate owing to action of funnel gases and/or immersion in sea water. Must be non-hygroscopic and the surface should be such that the settlement of moisture does not produce a continuous film. Surface must not be damaged by electrical flash-over.

(L.) *Receiver Power Supplies and Arrangements.*—The main receiving apparatus for heavy ships is installed in a silent room which forms a portion of the main wireless telegraph office. It has been laid down as a general policy that all receiving instruments shall be operated independently of the ship's mains, and the power supplies for the anodes and filaments have for this reason been taken from accumulators. Two complete sets of batteries are supplied for each office. The power for charging these batteries is taken from the 220- or 110-volt d.c. ship's mains. Motor-generators are installed for charging the low-voltage filament batteries, the anode batteries being charged directly from the mains through a suitable resistance. The control gear with fuses is mounted on a special switchboard which also contains the switches for the auxiliary 20-volt ship's supply for operating the buzzer circuits and supplying the secondary lighting circuit for the wireless telegraph office.

One common filament battery and one common anode battery are employed for all the models in a single receiving outfit. The earlier designs of models used bright-emitter valves employing 6 volts for the filament battery, but these models are being gradually converted to use a special dull-emitter valve having similar characteristics. The newer models have been designed to employ types of manufacturers' dull-emitter valves which have been found to be satisfactory, and a general review of the market led to the decision to adopt a filament battery of 4 volts. The common anode battery has been usually limited to 50 volts owing to weight and space considerations. A typical lay-out of long-wave naval receiving gear for a ship's office is indicated in Fig. 24, the plans in Figs. 5, 6 and 7 indicating the general lay-out of the receiving bays. Each bay is supplied from the common anode battery via a cushioning unit to prevent interference.

The question of adopting alternative power supply systems to the above accumulator systems has received considerable attention, and the earlier policy of adopting battery supplies entirely has undergone some revision. Experimental investigations are at present in hand with rectified alternating current and with d.c. generators as sources of supply (with or without a floating battery). If floating batteries are not used these systems must be capable of being operated from either the 220-volt d.c. or the auxiliary 20-volt ship's mains in order to provide for emergencies, but if floating batteries are used these in themselves form the emergency supply. The supply of anode voltage to receivers does not appear to present any insuperable difficulties, but the importance of good voltage regulation for a filament supply to dull-emitter valves in a central receiving room when the filament current may be changed suddenly from 5 amperes to a few milliamperes renders the problem much more difficult. It is essential to arrange for automatic voltage-control devices to be fitted in the 220-volt or 20-volt busbar supply to cover the wide variations in voltage which may occur in normal ship routine, whilst the inherent regulation of the motor-alternator or d.c. motor-generator must be very small. The best arrangement as regards regulation is probably a motor-generator system with floating battery, and in this case the floating battery is available for use alone in emergency; on the other hand the rectified a.c. system has considerable advantages, especially as regards reduction of interference.

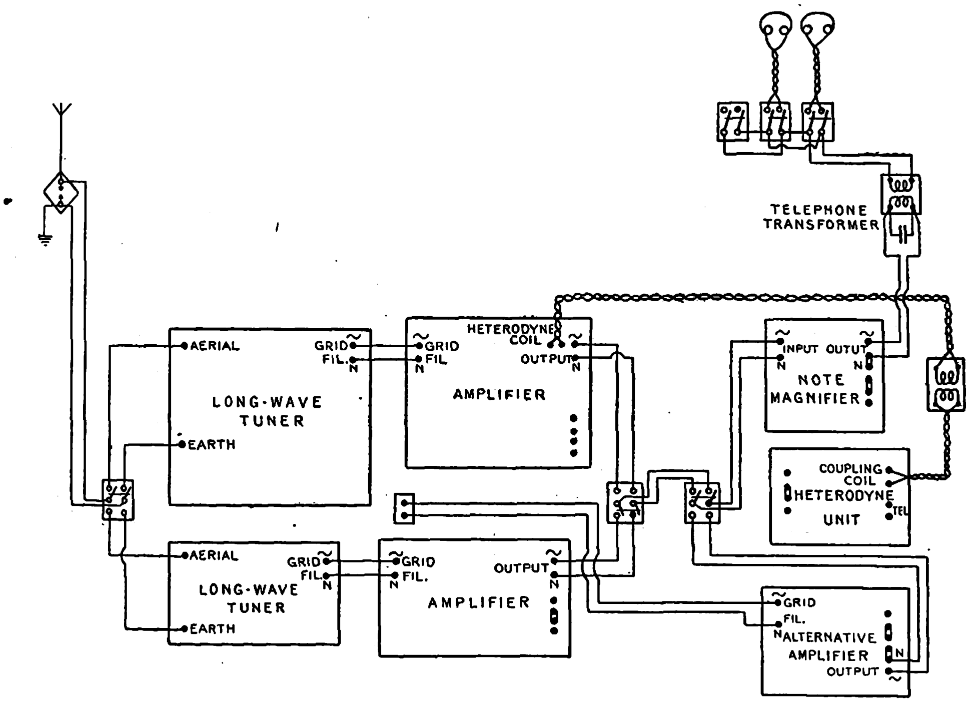

FIG. 24.—Arrangement of receiving model outfit.

The wiring and arrangements of the receivers to reduce interference has to be very carefully carried out; it may be interesting to enumerate here some of the chief interference problems which arise:—

(a) Mutual interaction from adjacent receivers, due to (i) common anode and filament supplies, (ii) local heterodynes.
(b) Morse-key clicks.
(c) Direct interference from transmitters adjacent to the receiving room.
(d) Interference between wireless telegraph offices in a ship, arising from mutual coupling between aerials.
(e) Faults such as earths or poor insulation on lighting supply leads, battery leads or fan leads introduce irregular low-frequency noises.
(f) Aerial down-hauls and stays which cross one another and rub are a serious cause of interference, especially to short-wave reception.
(g) Valve noises due to vibration, particularly in small ships.
(h) High-frequency interference from incoming cables which are connected to running machines.

The problem of interference from running machines is found to be especially troublesome, and in this connection the importance of good workmanship in the commutators and slip-rings of these machines in order to reduce sparking and ripple voltages cannot be over-emphasized. Sparking at a commutator may radiate wireless waves directly to the central receiving room. In addition, sparking or machine ripple may set up high-frequency oscillations along the cables, and, if any of these have a direct conducting path to the central receiving room, serious interference to both long- and short-wave reception may result. For the case of machines with poor brushgear design the effect of brush chatter in setting up high-frequency interference in this manner has proved especially troublesome. It has been found necessary in certain cases to fit low-pass filter units not only in the output but also in the input, i.e motor circuits of machines, to reduce this trouble.

(M.) *Receiving Aerials.*—The aerials employed for long-wave reception range from the main aerial of a ship to a short single wire. The aerial in use may be connected to the tuner in the office either by the central conductor of a long trunk or by a lead-cased cable which may have a length of the order of 150 ft. The effective capacity of the aerial receiving system may therefore vary over very wide limits, and the design of the aerial tuning circuits for a given receiver must be arranged to cover this wide variation. There is a considerable loss of receiving efficiency as the length of cable increases. More recently, cables having air and paper dielectric, and therefore much less capacity per unit length, have been employed with success in place of rubber cables.

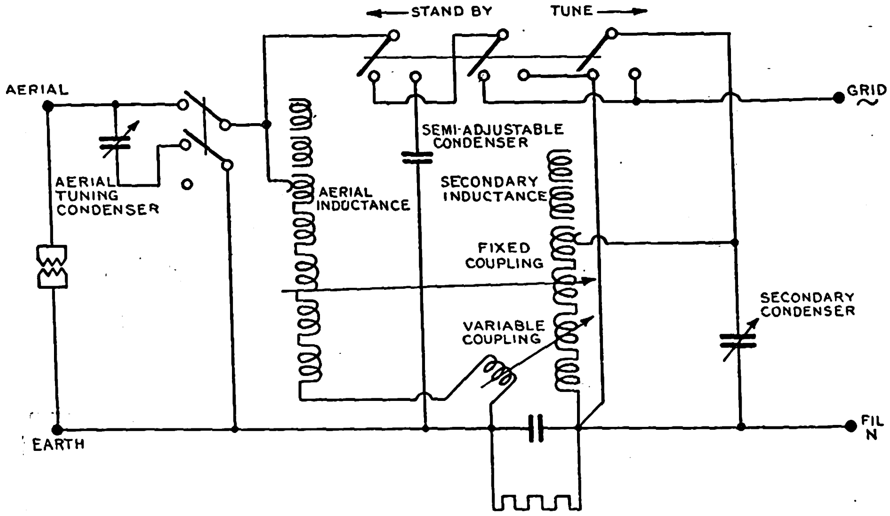

Fig. 25.—Schematic diagram of long-wave tuner.

(N.) *Receiver Design for Wide Frequency Bands.*

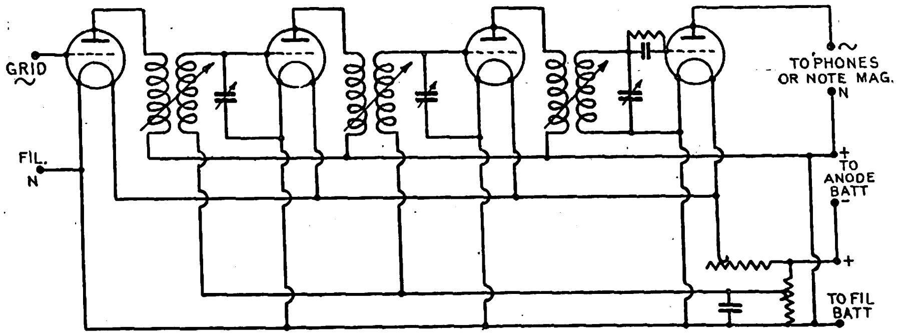

Fig. 26.—Schematic diagram of long-wave amplifier.

(i) *Long-wave receivers.*—Reception over the band of waves covering 12·5 to 6 000 kilocycles per sec. (24 000 to 50 m) has been provided by three ranges, viz. 12·5 to 600, 460 to 2 000 and 1 500 to 6 000 kilocycles per sec. (24 000 to 500, 650 to 150, and 200 to 50 m). The earlier policy was to adopt a unit form of assembly and construct a separate tuner and a high-frequency amplifier for each of these ranges. Also a standard 3-stage note-magnifier and a heterodyne to cover the range 12·5 to 2 500 kilocycles per sec. (24 000 to 120 m) was developed. Thus, any long-wave naval receiver included the appropriate tuner unit and high-frequency amplifier. The tuners are of the two-circuit magnetically-coupled type, and are fitted with a "stand-by" and "tune" switch. In the "stand-by" position the aerial circuit alone of the tuner is in use, so that quick searching is possible. In the "tune" position the closed secondary circuit is added to obtain selectivity and the inductive coupling can be loosened to any desired extent. In most cases, arrangements are made for listening-through on the wavelength being transmitted. For special purposes, such as direction-finding and submarine reception, where very high amplification combined with very quick searching is desired, special high-magnification non-selective amplifiers have been developed. Also, special tuners have been developed to allow for the high damping and high capacity to earth of loop-aerial systems when used in submarines.

Figs. 25 and 26 illustrate the circuit arrangements of one of the naval long-wave tuners and amplifiers which has had considerable application. The tuner comprises two tuned magnetically-coupled circuits and is designed for

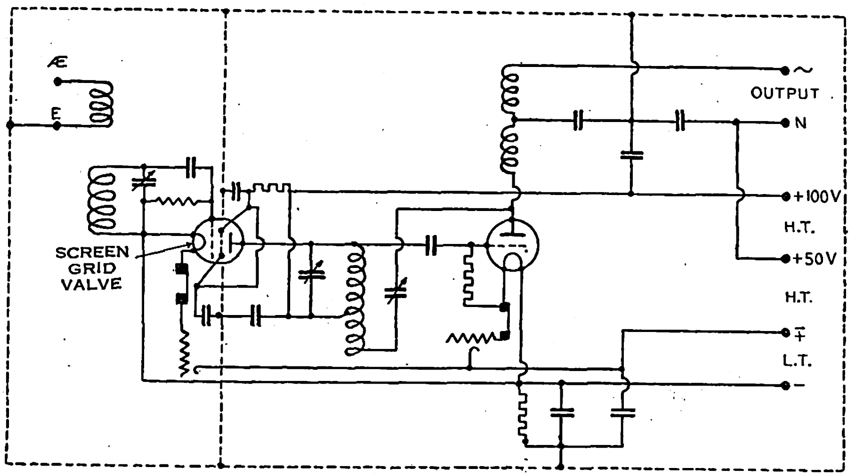
(i) tuning aerials having widely varying capacities for the entire range of 12·5 to 600 kilocycles per sec. (24 000 to 500 m), or

(ii) tuning as an acceptor circuit for the higher frequencies above 60 kilocycles per sec. (5 000 m).

A "stand-by" and "tune" switch is provided whereby the amplifier can be connected across the aerial tuning inductance when in the "stand-by" position, and across the secondary inductance when in the "tune" position. When in the "tune" position, a condenser having a capacity equal to that of the first valve of the amplifier and of the leads is connected across the primary inductance, thus obviating a change of tuning of the aerial circuit when switching over from "stand-by" to "tune." The secondary circuit is short-circuited and earthed in the "stand-by" position.

The amplifier circuits shown in Fig. 26 are designed for high amplification and selectivity. The entire range is covered by a number of range boxes which can be fitted into the amplifier. A separate heterodyne is employed which is coupled into the anode circuit of the first valve, thus to a great extent obviating radiation from the aerial.

For certain bands of waves, special provision has to be made for quick change from one wave to another, and this may be provided for either by the use of adjustable stops on the variable-condenser dial for cases where the change is small, or by change-over from one circuit to another for cases where there is a large difference between the two waves. The requirement that the majority of naval receivers must be non-radiating, necessitates an increase of circuit complications and in many cases increases the number of valves required for a given amplification.



DOTTED LINE REPRESENTS SCREENS ALL ROUND

FIG. 27.—Short-wave tuner amplifier.

More recently the general policy of the design of receiving gear has been modified, the unit construction being departed from to a considerable extent. The later designs of amplifiers now include note-magnification and separate heterodyne in one unit, and in the case of reception on longer waves of the order of 600 m and above, special provision is made for multiple reception on one aerial.

(ii) *Short-wave receivers.*—To cover the short-wave requirements, two types of special tuner-amplifiers have been developed, one a simple oscillating detector with two stages of note-magnification and no high-frequency amplification, the other an oscillatory detector preceded by a stage of high-frequency amplification to prevent oscillations from the detector from reaching the aerial and being radiated. Also, receivers have been developed employing a detector valve operating on the threshold of oscillation in conjunction with a separate quenching valve. For automatic reception at shore stations, a special circuit has been developed using the double heterodyne principle. As regards short-wave reception in ships, the fact that reception in general has to be carried out via cables or aerial trunks introduces difficulties due to the fact that for certain waves these may tune as transmission lines. The effects of this may usually be greatly reduced by the use of very loose aerial coupling, although loss of signal strength is thereby occasioned, especially for the case of interrupted-continuous-wave signals.

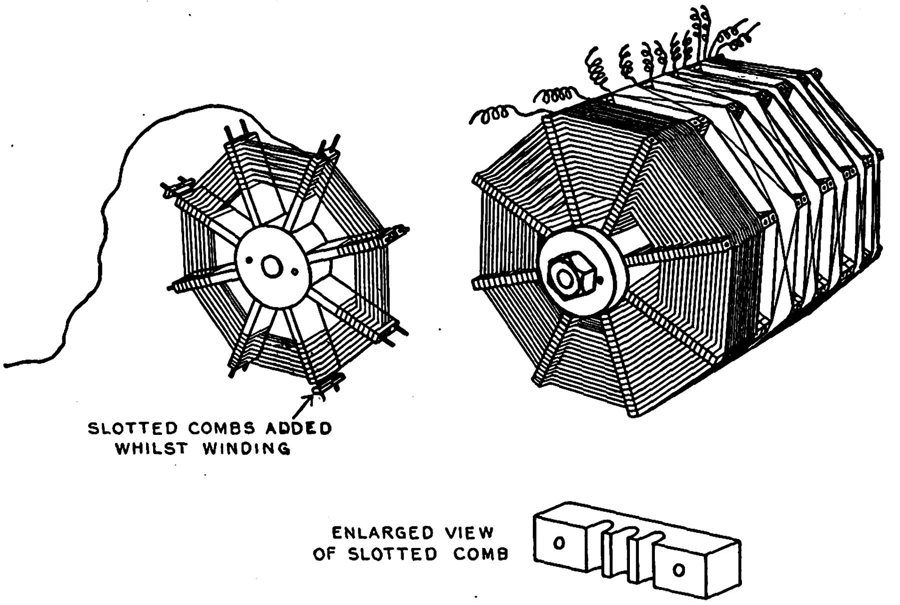
A typical design of non-radiating short-wave receiver for ships is shown in Fig. 27. A screen-grid valve is employed in the first stage, followed by a detector valve with reaction which is used as an autodyne for continuous-wave reception. A separate note-magnifier is used behind this model. Despite the use of the 4-electrode valve, there was found to be coupling between the tuned grid and tuned anode circuits. This coupling was reduced by introducing a very small condenser between the tuned grid circuit and the grid of the valve.

(O.) *Receiver Components and Assembly.*—The reliability in performance of receiving instruments for naval use is naturally of first importance. The apparatus has to be used in all climates, and, whilst every effort is made to reduce size and weight, instruments designed for use in H.M. ships are generally of a more substantial construction than is considered necessary for shore work.

A number of parts, components and units which lend themselves to assembly in various ways for various purposes have been developed. These are embodied in the instrument designs, with the result that certain standard practices tend to develop for naval work, with a consequent saving in cost and in the time required for production. Where the quantities required are large, mouldings, die castings and stampings are used in these parts, the necessary stock being held by the Admiralty and issued to contractors as required. In addition, commercially produced components which are standardized in the trade and suitable for the required purpose are used whenever possible.

The adaptable receiving components specially designed include an adjustable condenser with die-cast fixed and moving vane units and with moulded end plates, a series of dial switches and a series of barrel-type switches each capable of assembly for many varied purposes, filament rheostats and potentiometers, a slow-motion dial, grid leak and anode-resistance holders.

The adjustable condenser can be assembled to either 0·5, 1·0, 1·5 or 2·0 jars'* maximum capacity. It is of the twin pattern in which two sets of moving vanes, insulated from one another and mounted on opposite sides of the spindle and in the same planes, move between similarly mounted fixed vanes. Each set of moving vanes is connected to one of the sets of fixed vanes. This construction is well known and gives the maximum capacity change in a given space. The vanes are stamped from sea-resisting aluminium alloy and are held together in forms die-cast on to them. The units are assembled between end plates moulded from insulating material. These end plates carry the bushes for the spindle. The moving system is capable of adjustment endways for centring. The whole provides a strong and rigid construction capable of being assembled to a high value of maximum capacity for the space occupied, with a mechanically balanced moving system. The minimum capacity is of a fairly low order (0·02 to 0·05 jar). These condensers are not particularly suited for short-wave receiving work, and other types are being developed for this purpose.



SLOTTED COMBS ADDED WHILST WINDING
ENLARGED VIEW OF SLOTTED COMB

Fig. 28.

The dial-type switches are intended for mounting directly on the faces of instruments, and the contacts and brushes are exposed. The barrel-type switches are mounted behind the instrument front. They are self-insulated and can be mounted on metal panels. They take up much less panel space than the dial type. Both types of switch can be built for many purposes.

The slow-motion dial is worm-geared with a micrometer thimble on the worm shaft. The worm is held in close mesh with the wheel by a spring, and provision is made to enable it to be immediately disengaged to permit quick setting. The design is primarily intended for wavemeters and receiving instruments requiring a high accuracy of adjustment.

A vertical and a horizontal anti-vibration 4-pin valve-holder have also been designed specially to suit service requirements. The features of these are that provision is made for locking-in the valve, damp and dust are excluded and the connections are enclosed. The valve-socket block is carried on rubber to provide an effective cushion with damping. The holders are designed to enable the rubber cushion to be replaced from the front and without disconnecting the valve-holder.

As regards the inductance coils for long-wave tuners, an endeavour is made to obtain efficient coils with a minimum of self-capacity. The theoretical maximum efficiency cannot, in general, be obtained, however, owing to limitations imposed by the permissible size of the instrument and by manufacturing conditions. In general, all coils are space-wound, one form of winding which has been adopted being shown in Fig. 28. The wire used in this case is 9/36 S.W.G., each strand being enamelled and silk-covered. The use of enamelled wire, each strand silk-covered, was found in practice to give a higher efficiency than the use of enamelled wire only due to the elimination of broken strands with the additional silk covering. Smaller coils are, in general, space-wound with 9/36 S.W.G. wire on threaded formers for ease of manufacture. When very short wavelengths are in question, losses in the former become of more importance than those in the wire. Hence solid wire is then used. For naval purposes the use of coils entirely without solid formers is impracticable, and a compromise has been reached by the use of ribbed formers, the wire being held in threads cut in the ribs. Thus, each turn of wire is supported in air and only touches the actual ebonite former by ribs on the latter. This construction has been found to give satisfaction since, in addition to reducing losses generally, it forms a means of obviating the difficulties due to the formers "sweating" in hot climates.

---

* 1 jar = 1 000 cm.

Receiving instruments are mounted on bulkheads, and the space available is very limited. Consequently, controls must be on the face of the instrument, and it becomes an advantage that all parts shall come away with the instrument front. For this reason it is usual to provide a removable reversible cover which protects the front while the instrument is in transit and also serves as a bracket for securing it to the bulkhead when in use. In the later designs, the box and cover are of cast sea-resisting aluminium alloy, and the instrument front is of a similar rolled alloy.

It may be of interest to describe a small point in the design of variable inductances and condensers. Naval apparatus has hitherto been so designed that right-hand rotation gives an increased scale reading and indicates an increase of capacity or inductance and wavelength. In accordance with the decisions reached at the Washington Radio Convention the Navy has now adopted the use of kilocycles and consequently for the above apparatus a right-hand rotation corresponds to a decrease of frequency. For present and future developments of apparatus it has now been decided that right-hand rotation, corresponding to increase of scale reading, shall give increase of frequency. Consequently it has been necessary in a number of cases so to re-design the movements of condensers and inductances that right-hand or clockwise rotation gives a decrease in capacity or inductance.

(P.) *Direction-finding.*—The application of wireless telegraphy to direction-finding has great tactical importance. We may summarize the principal uses of direction-finding as:—

(1) Ascertaining the direction of enemy ships or aircraft.
(2) Checking the position of our own ships or aeroplanes making reports.
(3) Assisting aeroplanes in reconnaissances.
(4) An aid to navigation.

The type of system which is fitted in a particular ship largely depends on the structure of the ship. Just as a magnetic compass placed on board a steel ship is liable to considerable errors due to the magnetism of the ship (which errors have to be suitably corrected), so also a direction-finder is affected by the ship's structures and needs adjustment and calibration before reliable bearings can be obtained, and special correction devices have to be fitted for this purpose as with a compass.*

As a general rule it is the practice to fit the Bellini-Tosi system consisting of two loops in planes at right angles. Sometimes, however, where no suitable loops can be rigged, a rotating frame coil is fitted. Experience has shown that for a frame coil to be a success it must be placed in a position very well clear of metal work and preferably as high up as possible. In order that the coil may be conveniently rotated, the operator and instruments must be housed quite near to the coil, and sometimes this may limit very seriously the positions possible for the coil.

The Bellini-Tosi system is always fitted with one loop in the fore-and-aft line and the other loop exactly athwartships. To get the best results, regard must be paid to the positions of all large masses of metal in the vicinity of the loops, and generally the aim is so to place the loops as to secure the greatest possible symmetry with respect to the whole metal work of the ship. The loop run fore and aft is the one which invariably gives the greatest trouble in this respect.

The best position for the office, from a purely wireless point of view, is immediately beneath the aerials, but attention must be paid to other factors, such as weight distribution, vulnerability and compactness. For these reasons it is often necessary to have the instruments at a considerable distance from the aerials to which they are connected by cables. A common position for the operator and instruments is either the main or auxiliary wireless office. For the shorter waves, however, the price paid as regards accuracy for this convenience of organization and supervision is heavy, and offices immediately beneath the aerials are capable of much better accuracy.

(Q.) *Direction-finding Instrumental Design.*—The primary factors which govern the design of the receiving instruments for use in direction-finding are:—

(i) True bearings must be obtained without elaborate corrections or calculations.
(ii) Considerable amplification.
(iii) Ability to search rapidly over a band of waves so that a rough bearing may be obtained even though a transmission may last only a few seconds.

To meet these difficult requirements as far as possible, the moving element of the goniometer or frame coil is made as light as practicable to increase the speed at which a bearing can be taken, and generally the receivers have an unselective position suitable for quick search and a much more selective position for accurate work on a given band of waves.

The directional determinations are usually made by ascertaining the angle at which the search coil in a goniometer or a frame coil has to be set to give the minimum strength for the incoming signal. It is usual to find this angle by taking two readings at equal strengths, one on each side of the position of minimum strength, and to deduce the mean of these readings. To facilitate the determination of the mean value and to eliminate calculation, the naval service radiogoniometers and training units for frame coils are fitted with an automatic angle-dividing device. An additional rotatable scale is also provided which is driven by, and held in step with, the master gyro-compass. Thus, a bearing relative to the ship's head can be taken directly on the fixed scale, and true bearings are indicated directly on the rotating scale, no calculation being required for either. These two refinements, introduced into naval designs several years ago, greatly reduce both the time required to take a bearing and the error.

---

* C. E. Horton: "Wireless Direction-Finding in Steel Ships," *Journal I.E.E.*, 1923, vol. 61, p. 1049.

The ordinary direction-finder does not differentiate between the true bearing and one differing from it by 180°. For tactical purposes it is essential to be able to determine the absolute direction, and "sense finders" are fitted for this purpose. In the case of the Bellini-Tosi system of loops the sense finder is a separate unit attached to the receiver and is not in use when an accurate bearing is being taken. It is subsequently switched into action to determine which of the two readings 180° apart is the correct one. Separate sense-finding aerials are not normally used but sometimes when the office is at a great distance from the Bellini-Tosi loops an auxiliary aerial of the open type is necessary; this is usually a single vertical wire. For the case of a rotating coil or a system of fixed coils it is usual to have a separate sense-finding aerial, and the sense finder is incorporated as a part of the receiver.

Part (4). ORGANIZATION AND DEVELOPMENT PROCEDURE.

The responsibility for the experimental development and adaptation of the apparatus for naval communications rests with the Captain, H.M. Signal School, Portsmouth, where a staff of naval signal and civilian officers work side by side. The naval officers are attached to the Signal School for short periods only, usually of the order of two years, and in this way there is a continuous flow of officers from ships at sea who have intimate and up-to-date knowledge of the performance of apparatus in use or under trial at sea. These officers are able to state the broad requirements to which new apparatus should conform for success under sea-going conditions, and they co-operate with the civilian officers to ensure that these requirements are fulfilled.

The Director of the Signal Department, Admiralty, is in the closest touch in all signal matters with the Captain, H.M. Signal School, and is in direct touch with the Board of Admiralty; the reports from the various Commanders-in-Chief at sea covering wireless telegraph apparatus and naval communications are considered by the Director of the Signal Department, and the policies to be adopted as a result of these reports are formulated by him, after consultation with the Captain of H.M. Signal School, for the approval of the Board of Admiralty. In this way it is ensured that the experimental work of the Signal School is in accordance with the most recent sea-going requirements.

The experimental scientific staff of the Signal School are pooled under the Director of Scientific Research for the Admiralty, whose sphere includes all matters which relate to the supply and general distribution of the scientific civilian staffs for naval experimental and research purposes.

A close liaison exists between the Signal School and the other Government and industrial organizations, such as the Radio Research Board, the National Physical Laboratory and the British Engineering Standards Association. Representatives for the Admiralty are appointed from H.M. Signal School to various committees dealing with the work covered by the above organizations. The contact with the latest experimental and research work, dealing especially with wireless, has proved of great value to the Signal School.

Apart from the relations which naturally exist between the various scientific staffs of the Admiralty which are lent by the Director of Scientific Research to various naval establishments, a close liaison with the other military services is maintained by means of the main Wireless Telegraph Board Committee and the experimental sub-committee of this Board. These committees meet at frequent intervals and discuss service experimental developments. In addition, regular visits are interchanged with the service experimental establishments and arrangements are also made whereby, as far as practicable, components are standardized for inter-service use.

As stated above, the responsibility for development and design of apparatus in accordance with Admiralty policy is vested in the Captain, H.M. Signal School. Following on the production and satisfactory tests of first experimental models, first in the Signal School laboratories and then at sea, the final designs and specifications for the components are prepared and competitive tenders invited. The apparatus delivered from firms is tested for acceptance by the Signal School, and is later installed in ships under the direction of Signal School fitting-out officers.

In preparing the final designs of apparatus, commercial methods of production and workshop practice are kept in view, and every effort is made to confine the demand to common processes. At the same time, a high standard of workmanship is invariably called for in the specifications to ensure reliability of operation under sea-going conditions. B.E.S.A. standards are always adopted whenever possible, but proprietary articles are not usually embodied in designs for Service use unless they are of sufficient outstanding merit to out-balance the disadvantages of dependence on any particular source of supply.

Finally the authors desire to emphasize the debt owed, not only to members of the Service establishments but to manufacturers of equipment, who by their cordial co-operation have contributed to the ideal which all have in mind, that is the efficiency of the British Navy.

The paper is published with the permission of the Board of Admiralty. The authors desire to thank the Captain, H.M. Signal School, Portsmouth, for assistance in the preparation of the paper and for the use of diagrams prepared for Admiralty wireless telegraph handbooks. In addition, they would express their indebtedness to the members of the Civilian and Naval Experimental Staff of H.M. Signal School who have assisted in the preparation of the paper.

DISCUSSION BEFORE THE WIRELESS SECTION, 4TH DECEMBER, 1929.

Commander J. A. Slee: As the paper suggests, wireless communication in the Navy started with what is called a "plain aerial outfit," with which it was very important to maintain the standard of insulation in the aerial, which consisted of a length of wire very heavily insulated with rubber; I think the rubber was actually put on by hand. Next we used a circuit coupled between the transmitting gear and the aerials. There were two separate transmitters and two separate receivers making two separate sets of different wavelengths, which were then called A and B "tunes." There was no official transmitting apparatus in those days; we had a complete and properly constructed receiver—of the coherer type, of course—but we had to build up our own transmitters to specifications supplied, and to arrange with the carpenters to build various wooden formers, in the construction of which no metal was to be employed. Rubber-covered wire was used. There was very keen competition between ship and ship. Attempts were made to use alternators instead of batteries, employing the coil as a transformer. We had no alternators and very few ventilating fans, the latter being regarded as a great innovation at that time. Then followed what was called C "tune," which was a set of apparatus, not a specific wavelength, and we considered this to be a great advance. We used a $2\frac{1}{2}$-kW motor, and, with an open spark-gap, the spark passed with a very loud report. With the object of increasing ranges, we tried flying a kite at the end of a long piece of wire over the end of the aerial, and obtained some extraordinary results which, however, did not last for very long, because the kites were not really strong enough for the purpose. The early coherer receivers were followed by magnetic detectors, and that marked the beginning of audible reception. In those far-off days there was no telegraphist branch in the Navy: the torpedo officer was placed in charge of the wireless apparatus. After the magnetic detectors, crystal receivers were introduced. The first crystal used was a dull red stone, named zincite. Then came electrolytic detectors, which we constructed for ourselves; we made up half a dozen at a time and tried them against one another. I think we can all feel a considerable amount of pride in the state of efficiency to which wireless communication in the Navy has been raised since the days of which I have been speaking.

Prof. C. L. Fortescue: For those members who have been in any way connected with the Naval Service the paper has an interest from the historical point of view, but to the many who have not been intimately in touch with the development of naval wireless telegraphy the interest is in the insight which the paper gives into the conditions under which naval wireless is carried on. These conditions are very different from any found elsewhere. For instance, the paper describes cases of single ships in which six or eight lines of communication are all operating simultaneously. Then, again, many special difficulties are encountered—for example, the effect of sea-spray, or a heavy coating of salt over the insulators—which have not generally to be provided for in ordinary wireless installations. The skill called for in the design of the trunk leads on board ship is demonstrated in Fig. 23, and very few designers of apparatus for wireless reception are prepared to make provision for mounting their instruments on a deck which, as a result of gunfire, may whip a matter of about $\frac{1}{2}$ in.! It is not surprising that the apparatus has the external appearance of being complicated, because so much has to be crowded into a small space. The master oscillator, with its exact electrical balance all the way through, is interesting.

Commander C. S. Daniel: Naval wireless-telegraph work has certain definite characteristics. Point-to-point working is by no means the most important; the most important communications are those of the main fleet, which require absolute certainty of interception and wireless discipline. In making enemy reports, the reporting ship or aeroplane obtains an answer from only one other ship or aeroplane. The rest of the fleet must rely on interception. Further, on certain lines, the fleet flagship must be able to stop one ship, direct some others to carry on, and generally control traffic. This requires most efficient listening-through and good discipline. Given this, it should be possible to pass a short manœuvring signal to a fleet of 20 to 30 ships, obtain the answers, unit by unit, and be ready to make the executive signal in not more than $1\frac{1}{2}$ to 2 minutes. Obviously, naval apparatus must be so designed that sets will keep as constant a frequency as possible; and the most accurate wavemeters must be provided in order to avoid tuning discrepancies, which would be fatal to interception. A difficulty arises here, as ships may have to change their wavelength in order to avoid jamming by the enemy, or if there is congestion in their own fleet. The wavelength to which they change must be accurate. In shore-station practice we could provide as many sets as there were wavelengths required, but, as pointed out in the paper, space on board ship is very limited. The design of naval wireless-telegraph apparatus is far from easy. What degree of constancy can be obtained in a set which has to change wavelength almost instantaneously, and what developments are taking place to improve this? It may sometimes appear that naval specifications are very exacting; this, however, is bound to be the case. The importance of the battle of communications which precedes the fleet action cannot be over-estimated. Any defect in the wireless apparatus on board a ship of the fleet may alter the course of a war. The various things which *may* go wrong are very numerous: e.g. an earthed aerial, a burnt-out filament, some tuning error in transmitter or receiver, etc. Obviously, many features in naval design are dictated by experience afloat. Reference has been made in the paper to the new graduations for condensers and inductances, i.e. decrease of capacity or inductance with increase of scale reading. At present an increase of scale reading implies an increase in capacity or inductance. In the fleet all reference to waves is now in terms of kilocycles per sec.; and nothing is more irritating, when a fleet is being tuned in, than the fact that operators must decrease their scale readings when ordered to increase their frequency. Referring to rotating-coil direction-finders, the paper states that the operator should be near the coil and that this imposes certain limitations. It is hoped to overcome these limitations by leaving the coil up above, putting the operator and his gear below, and rotating the coil by remote control. At the beginning of the paper the authors mentioned the good results which accrued from collaboration between the scientist and the naval officer. I should like to support that statement whole-heartedly. The naval officer has to take the responsibility for communications at sea; he has certain apparatus to do it with and he must get the best results from that apparatus. I am glad to have this opportunity of expressing my admiration of the way in which the scientist meets the very exacting demands of the naval officer. So long as this co-operation exists, I think that naval wireless-telegraph communications will not be found wanting.

Dr. C. V. Drysdale: As Commander Slee and Prof. Fortescue have remarked, the difficulties associated with naval wireless work are great, and this ought to be fully recognized when comparing some of the devices with those in general use. The problem of supporting the valves against the severe shocks of gunfire and yet to permit of their rapid replacement is by no means an easy one; the need for working with a number of wavelengths and rapid change-over from one to another introduces difficulties which will be readily appreciated; and the proximity of large metal structures and the necessity for bringing the leads through trunks and glands add seriously to those difficulties. Accurate direction-finding is obviously of great importance to the Navy, and here the effects of the hull, superstructure and stays are most in evidence; but, by careful choice of positions and compensation, accuracy has been secured. On the scientific side the existence of a large fleet under a single organization and working over such a large range of frequencies has enabled much valuable information to be obtained on transmission under varying conditions. Such information is bound in time to have useful effect not only on naval but upon general navigational and commercial wireless, and we may be grateful to the officers and the scientific and technical staff of the Navy for the great advances they have made.

Mr. L. B. Turner: From this interesting description of past and present naval practice and apparatus I have noticed what is, I think, a rather remarkable omission: I see no reference to telephony. At first I thought this might be because the telephone, for strategic or other reasons, is debarred in the Naval Service; but the reference in Capt. Dorling's opening remarks to the Nelson of the future putting a telephone to his blind ear suggests that this is not so. The value of American whitewood in high-frequency fields was the discovery, I think, of the Post Office engineers in their work in designing the Rugby inductances. It is pointed out that its good qualities are destroyed by a humid atmosphere. Has impregnation of any kind been tried? Paraffin-wax suggests itself, but probably this is ruled out owing to the danger of fire. My experience with cellulose acetate in acetone suggests that this might be a suitable material to apply. The authors urge us not to forget that there is an optimum spacing between the strands of the high-frequency cable, and that the greatest possible number of strands in a given space is not the best. I should like to know how the correct spacing is provided, i.e. whether there is a whipping of spacing material on the conductor, and what material is used. Presumably cotton is unsuitable because of the enormous losses introduced unless it is very dry. Can the authors give us some details of a typical piece of one of these cables? The $\sqrt{N}$ rule for tapping a coil of N turns, given on page 250, I find novel and pleasing. An interesting point arises in connection with Fig. 21, showing the frequency-doubling circuits. I notice that there is no d.c. supply to the anodes. With back-coupling present, operation without d.c. supply seems possible, but does Fig. 21 represent actual conditions? On page 250 it is stated that the power factor of a good mica condenser is of the order of 0·4 of 1 per cent. This seems to be a very high figure. Good-quality mica condensers in laboratory work have very much lower power factors than this; and the Dubilier condensers at Rugby are believed to show a power factor of 0·02 of 1 per cent.* Fig. 26 shows an amplifier having 3 high-frequency stages, with a wavelength range of 24 000 to 500 m, and yet without any sort of neutrodyne retroaction balance. This seems to be a most remarkable receiver, and it would be very interesting if the authors could tell us a little more about it.

Mr. F. S. Barton: In regard to the re-design of condensers and inductances so that a clockwise movement gives a decrease of inductance or capacity, I should prefer to see standard practice retained and the scales arranged to read anti-clockwise for increasing frequency. This would have the advantage of still retaining the use of conventional commercial components, in which, as at present, a right-hand or clockwise motion gives an increase in the quantity being varied.

Mr. F. C. Lunnon: One problem in the case of a ship short-wave transmitter to cover a large range of wavelengths is that of providing suitable coupling arrangements between the output circuit of the transmitter and the aerial, so that at every wavelength one can transfer sufficient energy to the aerial fully to load the transmitter. The difficulty arises because in a ship one is forced to use a fixed length of aerial for the complete range of wavelengths. With a reasonable length of wire clear of the deck insulator, plus, in many cases, a considerable length of wire through an aerial trunk from the deck to the wireless cabin, the total length of aerial, measured from the transmitter, will usually be several wavelengths at the shortest wavelength and more than $\frac{1}{4}$ wavelength at the longest wavelength. It follows that the correct termination for the aerial varies rapidly over wide limits between the shortest and longest wavelengths of the transmitter, and unless means are provided for approximating to the correct termination then, however much mutual inductance be provided between transmitter and aerial, there will be many wavelengths at which only a very small amount of energy can be transferred to the aerial. When the total length of aerial is a whole number of $\frac{1}{2}$ wavelengths the correct termination is given by a tuned parallel circuit of inductance and capacity; and for an odd number of

---

* See *Journal I.E.E.*, 1927, vol. 65, p. 297.

¼ wavelengths a tuned series circuit is required. Moreover, the required values of capacity and inductance will themselves vary greatly over a range of, say, 14 to 70 m. I have found it necessary, for such a wave-band, to provide two variable condensers—one very small—and two equal inductances. Switches are provided to select either variable condenser and connect it in parallel, or in series, with the two inductances, which themselves may be switched in series or parallel. The latter provide the mutual inductance between transmitter and aerial. Even with these complicated arrangements the aerial, more often than not, is a reactive impedance requiring a large mutual inductance to transfer sufficient energy fully to load the transmitter. I was therefore surprised to note, from Fig. 19, that the coupling to the aerial for the short-wave transmitter, 14 to 70 m, is shown as a simple coupling coil. I should like to ask the authors whether in actual fact that is what is employed and whether, in that case, they do not experience many points in the wave-range where only a very small amount of energy can be transferred to the aerial. In ships where a very long aerial trunk is necessary between a short-wave transmitter and the deck, I should like to ask the authors whether the conductor through the trunk is used as a continuation of the aerial or as a feeder to the point where the aerial emerges from the trunk. The former makes for simple wave-changing but involves considerable losses at short wavelengths; the latter, of course, is a more efficient method but involves remote control of terminating apparatus located at the deck end of the trunk. I notice that reference is made to the extensive use of ebonite as an insulating material, both on receivers and transmitters. General experience of ebonite in tropical climates is that both its insulating and mechanical qualities deteriorate greatly. Mycalex, on the other hand, is free from both these defects. What is the authors' experience of ebonite in ships stationed for long periods in the tropics, and have they found mycalex generally satisfactory as a substitute for ebonite?

Mr. H. Faulkner: It seems to me at first sight that the protective arrangements provided on the transmitter are inadequate. There appear to be no overload relays provided on the switches, such as one would expect to see. The protective arrangements for the oscillating valves themselves consist simply of a single relay to protect the 3 valves which are connected in parallel. While I agree that such protection is adequate as protection, it is my experience that this arrangement is very often likely to cause needless delay because of the difficulty in tracing which of a number of valves has failed. My experience, perhaps, has been more concerned with cooled-anode valves, and the circumstances may be different; but certainly I would suggest that the fitting of a small indicator, if a relay cannot be fitted, to indicate which valve has taken an overload, would be an improvement. I have no doubt that valves do *sometimes* fail from loss of vacuum. I notice that horn-gap fuses are fitted in the rectifier. Are these the principal protective devices for the system in the case of a breakdown of the smoothing condenser, for instance, or other short-circuit on the supply, or is any other form of protection provided? If these are the only protective devices, I am interested to know whether they are completely satisfactory, and what kind of fuse wire is used. With regard to keying, I note that in Fig. 11 this is direct in the anode circuit. This seems to me rather a "hard" method of keying. A great deal of sparking must take place at the key when in that position in the circuit, and it would be practically impossible to do any high-speed work. Some time ago I tried a system of keying in the grid circuit and a.c. supply simultaneously, with the idea that the breaking of the grid circuit stopped the current, and the breaking of the a. c. supply prevented the undue rise of anode voltage from the rectifier through taking off the load. Some improvement of the sparking at the key might be obtained by such an arrangement. Further, no coupled circuit to the antennæ is shown; is this due to a lack of space, or to the fact that it is not found necessary? I should have thought that with large numbers of transmitters working on the same ship, and on a large number of ships comparatively close together working on widely different wavelengths, there would be considerable trouble from harmonic radiation. Referring to Fig. 13, it is observed that each valve is provided with its own grid leak. Have the authors any evidence as to whether this arrangement equalizes the load between the valves? Post Office practice has always been to provide a common grid-leak for the circuit. I do not think that individual grid-leaks can have any effect on possible spurious oscillations between the valves. In Fig. 14 the overload contacts on the anode relay, etc., are shown as opening the filament circuit—that is to say, when an overload occurs the filament of the valve is switched off. I should like to know whether that is found to be satisfactory. It is my experience that when a valve is very soft the overload may continue through the valve, even if the filament *is* switched off. With regard to Figs. 19 and 20, it seems remarkable that the arrangement provided for switching from short to long waves does not make the transmitter very unstable on the short waves. I should like to hear the authors' experience in this connection. I think that the frequency-doubler circuit should be made rather clearer in the diagram. What is the efficiency of this doubler circuit? I notice that the doubling takes place at high power; hence it would appear that it must be very effective, since otherwise much waste of power would take place.

Mr. G. Shearing and **Captain J. W. S. Dorling** (*in reply*): Commander Slee has given additional information relating to the earlier history of naval wireless communications and to some of the difficulties which were encountered in those days. One of the objects of the paper was to give a broad view of the requirements for naval wireless telegraphy apparatus and we are glad to note the remarks of Prof. Fortescue and of Dr. Drysdale in this connection. It is true that the varied requirements tend to make the apparatus look complicated; the limited space which is available for these requirements, particularly the requirement of the flexibility of sets over a wide wavelength range, necessitates the use of somewhat simple circuits. It is for this reason that coupled circuits for long-wave working are not usually employed in the high-power transmitters.

The necessity for rapid valve-change referred to by Dr. Drysdale has had to receive special attention, and the later designs of valve-holders for high-power sets enable any single valve to be replaced in a few seconds. Incidentally, the naval silica valve, which is largely employed for power transmitters, lends itself readily to replacement in the minimum of time.

The special requirements for naval ship working have been amplified by Commander Daniel, and these requirements emphasize the necessity for simple oscillatory-circuit apparatus. On the other hand, the control and operating circuits have to be fairly complex to ensure that the operations necessary for wave-change and for bringing various sets into use may be effected in the small time available for operating and manœuvring requirements. With regard to the need for extreme accuracy in the tuning of transmitters and the degree of constancy obtainable in a set which has to change wave almost instantaneously, the question can only be answered in general terms. The spark-transmitters formerly in use were tuned with carefully-calibrated wavemeters by skilled personnel, and no difficulty was experienced, since tuning was necessarily broad. The introduction of the valve transmitters for continuous waves or interrupted continuous waves, and the use of short waves, have naturally increased the difficulty of ensuring that all ships can transmit sufficiently accurately on any one of a number of waves. Wavemeters accurate enough for spark-transmitters lacked the necessary high degree of accuracy, particularly after extended use at sea. As a temporary expedient it has become necessary for one ship of the fleet, usually the flagship, to tune the transmissions of all ships to the same frequency; each ship, having noted the adjustments, can radiate the same frequency on subsequent occasions with reasonable accuracy. Improvements in wavemeters and the introduction of master-drive transmitters are leading to greater accuracy of initial tuning, although it is not yet certain that any sub-standard wavemeter of reasonable size, weight and simplicity, will be able to detect a small change of frequency as readily as can a receiver at a distance.

Mr. Turner has remarked upon the lack of reference to telephony in the paper. At one time it was thought that there would be great possibilities for wireless telephony in the naval service. Trial afloat showed, however, that the advantages were more apparent than real, except for certain definite applications. The main disadvantage is the lack of secrecy. Whatever system is used there can, at present, never be certainty that conversations cannot be overheard. Moreover, there can be no written record for future reference. The time taken to speak a message is often greater than would be sufficient to transmit the same message by morse, employing code, and the range of communication by telephony is less than the telegraph range. Again, even for the case when the morse is plain language the time taken is often less than for wireless telephony. Using wireless telephony, speech must be slow in order to avoid phonetic errors and repetitions. The use of wireless telephony in the naval service is therefore confined to those cases where secrecy is not essential and where direct communication between principals is required without intermediate links, or where conditions are such that it is not possible to arrange for operators trained in the Morse Code. With regard to American whitewood, impregnation with various bakelite compounds has been tried, but these have been found to be unsatisfactory. Experimental tests have been made of woods treated with paraffin-wax, also with cellulose-acetate in acetone, but the danger of fire has precluded their use. The heating adjacent to high-potential metallic contacts causes the solvent to give off a gas which is mainly hydrogen. This gas has a lower ionization-potential than air and therefore the danger of breakdown is increased. The experiments with paraffin-wax were definitely unsatisfactory. Also the addition of any form of impregnation to the wood provides an increase of permittivity and enhances the losses adjacent to high-potential metal contacts carried by the wood. An occasional flash-over has been found to destroy the insulation of wood so that replacement is necessary. In the case of ebonite, however, an occasional flash-over can usually be rectified by scraping away the burnt surface. A full discussion of the spacing of turns of stranded wire on a coil and of the effects of the size and spacing of the individual strands in the stranded wire has been published.* Although the effects of capacity between the strands and turns of a coil are not taken into account, the calculations give a valuable indication of the coil resistance to be expected. The size of the strand is usually fixed by manufacturing limitations. The spacing between the separate conductors of a strand is effected by enamel alone or by enamel together with a silk covering. The size of enamelled wire generally used is No. 38 S.W.G. When enamelling is employed alone, the separate conductors are liable to stretch, harden, and break during stranding and, in addition, the enamel may be rubbed at places so that contact with other strands is possible. Despite these disadvantages, large quantities of wire thus insulated are still used. For cases where it is necessary to ensure that the separate conductors are not broken, such as in the case of receiving coils using a smaller number of strands, No. 36 S.W.G. wire is used and each conductor is enamelled and then silk-covered. This affects the overall diameter of the wire and the spacing of the strands; difficulties are often encountered due to limitations of the space available for coils and for the tapping-points required. These limitations in many cases largely determine the design so that the actual resistance of the coil may have to take a secondary place, although its value is calculated as a check. Typical designs of stranded wire are indicated below:—

(*a*) 729/38 *Stranded Wire for Transmitter Coils.*—This is built up by stranding No. 38 S.W.G. enamel-insulated copper wires in groups of three (and continuing the operation). The lay of the groups should be right- and left-hand alternately. The stranded wire is covered with cotton braid which is coated with Ohmaline or Ozokerite. When assembling the wire without braided covering it was found that some of the wires snapped when bent over the combs in the coil-frameworks. These broken wires may cause brushing and insulation failure. The braiding overcomes this difficulty and provides a soft bed when bending the wire; also any broken strands are retained in place. In a few special cases transmitting-coils have been wound using wires with each strand silk-covered, but the cost of this is normally not considered to be justified.

---

* S. Butterworth; "The Effective Resistance of Inductance Coils at Radio Frequency," *Experimental Wireless and Wireless Engineer*, 1926, vol. 3, pp. 203, 309, 417 and 483.

(*b*) 9/36 *Stranded Wire*.—This wire is used in coils for receiving apparatus. It is stranded as described above, but each strand is enamelled and silk-covered. The chief function of the silk covering is to provide a soft bed for the wires when building-up during stranding and thus to prevent elongation, hardening and breaking.

We agree that the value quoted for the power factor of a good mica condenser is too high; this value should have been 0·2 of 1 per cent, to which value the figure has been corrected.

With regard to the amplifier and tuner shown in Figs. 25 and 26, these instruments were designed several years ago and have had a very wide application at sea. Apart from the frequency-range requirements, the necessary features include the following: (*a*) Satisfactory selectivity and high-frequency amplification. (*b*) No difficult adjustments, on account of the necessity for changing from one wave to another in a few seconds. (*c*) Ease of handling. These requirements naturally necessitate compromise. In general, high selectivity cannot be reconciled with ease of handling and quick wave-change, whilst very high amplification cannot be reconciled with stability over a wide range of frequencies. In addition, very high amplification is not of great practical value in ships because of the large amount of extraneous noise from running machines, aerial and stay vibrations, etc. The technical advantages of neutralization and its application to service receivers have been considered not only with regard to the receiver of Figs. 25 and 26 but also in connection with other models. Reference has been made in the paper to the fact that this receiver has had considerable application. It was designed several years ago to employ the naval R.7 valve which has an amplification factor of 7 and a grid-anode capacity of the order of 1 cm only. General-purpose valves of modern design have an amplification factor of the order of 14, and a grid-anode capacity of the order of 4 cm. Since feed-back is proportional (as a first approximation) to the product of amplification factor and grid-anode capacity, it follows that the need for neutralization is much less in the case of an R.7 valve than for one of a more recent type. Again, neutralization introduces at least one extra adjustment for the setting of a neutralizing condenser is, in general, different for different wave-ranges and may not even be constant over a single wave-range. Hence, if a neutralizing condenser is fitted, the stability of the receiver will be entirely in the hands of the operator. Failure to make this extra adjustment may lead to serious trouble, since when one receiver oscillates it may jam reception for other ships. The introduction of screen-grid valves is clearly a development for the later long-wave amplifiers, since these valves offer the possibility of high amplification without the trouble and difficulty of neutralization; later designs of long-wave receivers employ these valves.

With reference to Mr. Barton's remarks concerning the adoption of clockwise movement for inductance and capacities to correspond to increase of frequency, we think that Commander Daniel has stated the case for this convention as regards naval practice.

Mr. Lunnon has referred to the effects which occur when a fixed length of aerial is used with a short-wave band of frequencies. A conductor through a long trunk in a ship can be considered to be a transmission line leading from the transmitter to the aerial, and standing waves of current and voltage will be set up in it unless means are employed whereby the aerial and the transmitter-circuit impedances can be matched with the surge impedance of the trunk. Series or parallel connection of adjustable condensers at the coupling coil of the set constitutes one half of a suppression system and is certainly of value in getting more power into the aerial. These methods are employed in naval transmitters operating on narrow bands of frequency, but they are not used in the case of high-power short-wave transmitters working on the main aerial of a ship. Experience has shown that where the aerial system corresponds to a large number of ¼-wavelengths (as for main aerials), it is possible to put sufficient energy into it to obtain communication at the required ranges. We agree, however, that the employment of parallel or series condensers, possibly with additional coils at the coupling-coil, does increase the energy input to the aerial. In short-wave sets of lower power working through trunks to an aerial much shorter than the main aerial system, partial suppression has been employed (utilizing both the parallel and series systems of connections of variable condensers at the coupling coil of the set) when difficulty has been experienced in energizing the aerial. Where ship transmitters operate on a fixed wavelength, complete suppression of the standing waves has been employed. This, however, necessitates the insertion of a suitable tuning-circuit immediately adjacent to the main-deck insulator additional to the suppressing apparatus inserted at the coupling coil of the set. The naval use of "Mycalex" in standardized apparatus has not yet been sufficiently extensive to warrant a definite conclusion, but, so far as it has been employed in high-frequency circuits, the material has proved very satisfactory. Recent designs of adjustable high-voltage short-wave condensers, valve-holders, and coils, have employed "Mycalex" as insulation. The fact that the surface of "Mycalex" is not damaged by occasional arcing is a great factor in its favour. Our experience is that high-quality ebonite has proved on the whole more satisfactory than any other insulating material which, until recently, has been available for use with high-power coils under tropical conditions; we admit that it is far from being an ideal insulator. Aerial coils with ebonite combs have had years of use in ships under tropical conditions. It is not yet possible to say whether "Mycalex" will replace ebonite for use with high-voltage aerial coils.

In reply to Mr. Faulkner, the single overload relay system has proved adequate for the three transmitting valves employed in parallel in high-power ship transmitters. The envelopes of the silica valves can be seen from the gangway in front of the valve panels, and the glow resulting from a loss of vacuum is readily visible. In actual practice, however, valve failure from this cause is rare. The horn-gap fuses constitute the high-tension protection in case of any breakdown of the rectifier system, but it has also to be noted that the main circuit breakers in the primary d.c. supply to the main motor-alternators will also operate in the event of a severe overload. Fig. 11 shows that the anode key in the long-wave circuits is inserted between the transmitting-valve anodes and the anode blocking-condensers, the other terminal of which goes to the anode tapping-point on the aerial inductance. The valves used have fairly open grids so that this key cannot be employed for signalling unless suitable grid-potential control is also employed during spacing. This key opens the circuit during spacing, solely to ensure that there is no loss of received signal-strength from valve-damping across a portion of the aerial inductance when listening-through. The signalling-key of this transmitter is in the primary circuit of the a.c. supply and is the magnetic key shown in Fig. 10. The bobbin circuit for the anode key of Fig. 11 is placed across the front and middle contacts of the master transmitting-key so that the anode key always makes circuit before, and breaks after, the magnetic key for signalling. The d.c. control circuits are shown in Fig. 15. Interference troubles undoubtedly occur when the main ship transmitter is in use, and certain of the other aerials have to be earthed. Thus Fig. 17 indicates that the second office and the direction-finding office aerials can be earthed during transmission, but the transmitters of lower power can usually be employed simultaneously without serious interference to reception on any one of the lines. The reason for the adoption of separate grid-leaks for the particular transmitter circuit described in the paper was to avoid spurious oscillations which were found to occur when a common grid-leak was used. In this way the very high-frequency parasitic oscillation which occurred between the anodes and grids of the valves with a common grid-leak was avoided. The switching-off of the valve transmitting- and rectifying-filaments by excess current operating the overload relay has proved satisfactory and this system has been in use for over 10 years in various ship-transmitters. It should be observed that each of the rectifying valves takes a proportion of the H.T. supply voltage when the filaments are switched off. Thus the voltage stress is not across the transmitting valves alone. The combined long-wave and short-wave transmitter of Fig. 19 has been designed so that the valves are double-acting or in " push-pull " as regards the generation of high-frequency short-wave oscillatory current. The circuit arrangements are thus of symmetrical design and have proved stable with suitable neutralization of the valve anode-grid capacities. The chief difficulty in the design of this transmitter arose from the effects of secondary emission of the grids of the transmitting valves.

In answer to Mr. Turner's and Mr. Faulkner's remarks regarding the frequency-doubling circuit, Fig. 21, the circuits are neutralized by means of the adjustable condensers, so that there is no back-coupling. A H.T. supply to each stage is required and this is now indicated in the diagram. The overall efficiency of the combined circuits of Figs. 20 and 21 is less than that of the circuits of Fig. 20. However, when alternative transmissions on either frequency are desired the arrangements are useful and less costly than a second transmitter, while the extra space required is small. Transmissions can be made readily on either of the two wavelengths without tuning readjustments, so that operation is simple. A transmitter designed solely for the higher frequency corresponding to the doubler value would undoubtedly have a greater overall efficiency as regards H.T. power supply, but its initial cost would naturally be much greater than the cost of adding the doubler circuit to an existing transmitter. Again, other factors, such as the space available for transmitting apparatus, had to be taken into consideration when deciding whether a frequency-doubler circuit for an existing transmitter, or an additional transmitter, was to be employed.

THE VALVE-MAINTAINED QUARTZ OSCILLATOR.[*]

By J. E. P. VIGOUREUX, M.Sc., Graduate.

[From the National Physical Laboratory : communicated by permission of the Radio Research Board.]

(*Paper first received 24th June, and in final form 18th October, 1929.*)

SUMMARY.

A quartz resonator connected between the grid of a valve and either of the other electrodes gives rise to oscillations in the plate circuit when the constants of that circuit satisfy certain conditions. The frequency of the oscillations depends mainly upon the natural frequency of the quartz, and is, therefore, fairly constant when the temperature is constant. In addition to temperature effects, which are not considered in the present paper, variations of frequency can be produced by (i) variations of the air-gaps of the resonator, i.e. the air-gaps between the quartz and the two electrodes of the resonator; (ii) variations of the constants of the plate circuit; and (iii) variations of the inter-electrode capacities and conductances. The object of the investigation is the study of these variations, both theoretically and experimentally.

In the theoretical treatment, the quartz is replaced by a circuit made up of an inductance, a resistance and a capacity in series, the whole being in parallel with a second capacity. The validity of such a substitution has been studied experimentally by Dye.

The combination of quartz resonator, valve and plate circuit is represented by a network of admittances, from which three circuit equations are obtained; to these is added the fundamental equation of the valve. These four equations yield a single linear differential equation of the fifth order, with constant coefficients. In the case under investigation, it is only required to find the frequency and the amplitude of oscillations after the latter have reached a constant amplitude. This consideration affords a means of reducing the differential equation to one of the same type, but of the second order. From the latter equation, of which the general solution is known, formulæ are developed for the changes of frequency resulting from variations in the resistance and capacity of the plate circuit, in the resistance of the grid leak, in the inter-electrode capacities, and in the air-gap. These formulæ provide useful information as to the influence of each variable on the frequency, and can with advantage be applied to the choice of the best circuits and the best valve for a quartz oscillator.

As the oscillations build up after switching on, the average plate conductance of the valve alters gradually. When the amplitude of oscillation has reached its final value, the value of the average plate conductance is such as to annul the damping term, i.e. the coefficient of dy/dt in the differential equation. From this condition the average plate conductance can be determined for any values of the circuit variables. The amplitude of oscillations in the plate circuit is a function of this average plate conductance.

Formulæ are developed which give the conditions for the maintenance of oscillations, and an investigation is made of the variations of amplitude with variations in (*a*) capacity in the plate circuit, (*b*) resistance in the plate circuit, and (*c*) grid conductance.

Points of importance in the choice of circuits and valves are deduced from the formulæ and the theoretical curves.

Two types of quartz oscillator are investigated, namely, the cases in which the quartz resonator is connected between (i) the grid and the plate of the valve, and (ii) the grid and the filament of the valve.

A fairly complete experimental investigation is described. The admittances of the valve and of the circuits were measured, and the equivalent electrical network of the quartz was determined. The behaviour of the quartz oscillator was then investigated by altering in turn each variable in the circuits. The theoretical and experimental results are compared and discussed.

The paper does not deal with circuits especially devised for obtaining large outputs from quartz crystals. Its object is the study of the influence of the circuit variables on the frequency and on the power generated as regards the simple Pierce circuits.

INTRODUCTION.

W. G. Cady[†] and G. W. Pierce[‡] have shown that quartz resonators can be used for maintaining oscillations in a valve circuit. The frequency of the oscillations depends almost entirely on the natural frequency of vibration of the quartz, and is, therefore, very constant. The combination of resonator and valve circuit is known as a "quartz oscillator." Quartz oscillators are at present widely employed for controlling the frequency of wireless transmitting stations, in the same way that an ordinary master oscillator was used formerly, and give excellent results. They are also very convenient for calibrating wavemeters, and are extensively used for that purpose in America.

The circuits considered in this paper are all based on Pierce's circuit. A single valve is used, with the quartz connected between the grid and the plate, or between the grid and the filament, and, under certain conditions, oscillations are maintained in the plate-filament circuit. This latter circuit may be a high non-inductive resistance, of approximately the same value as the valve impedance; but for powerful oscillations an oscillatory circuit is used, made up of a condenser and an inductance coil in parallel, and oscillations are maintained for a wide range of condenser settings.

The type of connection in which the resonator is connected between the plate and the grid of the valve will be called the "plate-to-grid connection," and the other type the "grid-to-filament connection."

Besides temperature effects, which need not be considered here, variations in frequency are caused by (*a*) variations of the air-gap; (*b*) variations of the constants of the plate circuit; and (*c*) variations of the inter-electrode capacities and conductances.

[*] The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

[†] See Reference (1).

[‡] *Ibid.*, (2).

E. M. Terry[*] and J. W. Wright[†] have recently given a method of predicting the variations of frequency due to variations of the circuit constants. We are dealing here with the same problem and, in addition, an attempt is made to obtain an idea of the power to be expected for various values of the circuit constants.

(1) THEORETICAL TREATMENT.

The Fundamental Equations.

The circuit may be represented in a general way by Fig. 1, in which G_1, G_2 and G_3 represent admittances. They include the inter-electrode admittances as well as the admittances of external circuits.

Let g be the anode conductance of the valve and m its amplification factor. The fundamental equation of the valve is

$$i_1 + i_2 = g(v + me) \quad . \quad . \quad . \quad . \quad (1)$$

with the currents and potential differences indicated in Fig. 1.

It is assumed that the variations of current are such as would be produced by a straight-line characteristic for the valve. This assumption is never realized in practice, for, once oscillations start, they must of necessity increase in amplitude until the anode conductance g alters in such a way that the exponential term in the solution of the differential equation connecting current and time becomes unity. Here, however, it is assumed that g does not change. It is also assumed that the conductance between the grid and the filament is constant throughout a complete oscillation. This is not, in general, the case, because for part of the cycle the grid is at a negative potential with respect to the filament, when the conductance is only that of the grid leak; and for the rest of the cycle it is at a positive potential with respect to the filament, and the conductance becomes larger owing to thermionic effect.

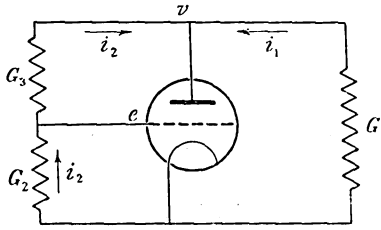

FIG 1.

In addition to equation (1) we can write down the three circuit equations:—

$$\left.\begin{aligned} i_1 &= -G_1 v \\ i_2 &= -G_2 e \\ i_2 &= -G_3(v - e) \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad (2)$$

In general, G_1, G_2 and G_3 will all contain the differential operator D and the resultant equations in i_1, i_2, v or e will be identical, which means that the complementary function is of the same form for i_1, i_2, v and e.

From equations (1) and (2) we obtain

$$\begin{vmatrix} 1 & 1 & -g & -mg \\ 1 & 0 & G_1 & 0 \\ 0 & 1 & 0 & G_2 \\ 0 & 1 & G_3 & -G_3 \end{vmatrix} y = 0$$

where y stands for either i_1, i_2, v or e.

This determinant gives the simple equation

$$\left[G_3\left\{G_1 + G_2 + (m+1)g\right\} + G_2(G_1 + g)\right]y = 0 \quad . \quad (3)$$

Expressions must now be obtained for G_1, G_2 and G_3 in terms of the circuit constants and of the valve constants.

Consider G_1 first; it is a circuit similar to that in Fig. 2, in which the capacity C includes the capacity C_1 of the plate to the filament. The capacity C is therefore always greater than zero. The inter-electrode plate-to-filament conductance is denoted by g_1.

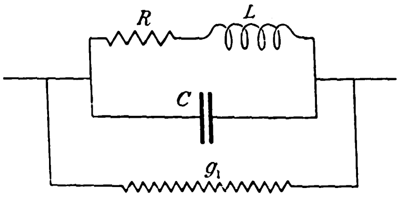

FIG 2.

The conductance of a capacity C is denoted by DC, and that of an inductance L by $1/DL$, where D stands for the differential operator d/dt.

We therefore have

$$G_1 = \left\{1/(R + DL)\right\} + DC + g_1 \quad . \quad . \quad (4)$$

We also have to evaluate G_2 and G_3. Let g_2 and C_2 be the inter-electrode conductance and capacity between grid and filament, and let g_4 be the conductance of a grid leak. That part of G_2 due to the above quantities is $(g_2 + g_4 + DC_2)$.

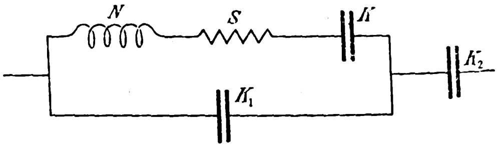

FIG 3.

Let g_3 and C_3 be the inter-electrode conductance and capacity between the plate and the grid. That part of G_3 due to them is $(g_3 + DC_3)$.

The admittance of the quartz circuit is added to either of these, depending upon whether the quartz is placed between the plate and grid, or between the filament and grid.

It has been shown by W. G. Cady,[*] D. W. Dye[†] and others, that a fairly accurate electrical representation of the behaviour of the quartz is given by the circuit NSKK$_1$ of Fig. 3; the capacity K_1 is approximately equal[‡] to the static capacity between the two faces of the quartz perpendicular to the electrical axis e, whilst K is only an equivalent capacity depending upon the piezo-electric and elastic constants. The resistance S accounts for the damping of the quartz vibrator, K_2 is the capacity of the air-gap between the electrodes, and K_3 the stray capacity between the electrodes and between the leads.

---

[*] See Reference (3). [†] *Ibid.*, (9).

[*] See Reference (1). [†] *Ibid.*, (4). [‡] *Ibid.*, (5).

The admittance of the quartz will then be

$$DK_3+1\Big/\left[\frac{1}{DK_2}+1\Big/\left\{DK_1+1\Big/\left(DN+S+\frac{1}{DK}\right)\right\}\right]$$

$$=DK_3+\frac{DK_2(D^2NKK_1+DSKK_1+K_1+K)}{D^2NK(K_1+K_2)+DSK(K_1+K_2)+K_1+K_2+K}$$

Using Dye's notation, we obtain

$$K_1+K_2=K_t \quad . \quad . \quad . \quad . \quad . \quad (5)$$

Then the admittance of the quartz system is

$$D\left[K_3+\frac{D^2NK+DSK+1+(K/K_1)}{D^2NK+DSK+1+(K/K_t)}\cdot\frac{K_1K_2}{K_t}\right]$$

For a further simplification, let

$$D^2NK+DSK+1+\frac{K}{K_1}=\sigma \quad . \quad . \quad (6)$$

$$D^2NK+DSK+1+\frac{K}{K_t}=\nu \quad . \quad . \quad (7)$$

The admittance of the quartz is then given by

$$. \quad . \quad . \quad DK_8+D(K_1K_2/K_t)(\sigma/\nu)$$

The values of G_1, G_2 and G_3 are thus obtained in terms of the circuit constants and of the valve constants. It remains only to substitute these values in equation (3), and to use this equation to find the condition for maintenance of oscillations, the frequency, and the amplitude of oscillations.

Before dealing with the complicated equation resulting from the substitution of G_1, G_2 and G_3 in equation (3), consider the simple general equation of an oscillating system:

$$(D^2A+DB+C)y=0$$

The solution is obtained by solving the quadratic

$$\lambda^2A+\lambda B+C=0$$

which gives

$$\lambda=\left\{-B\pm\sqrt{(B^2-4AC)}\right\}/2A$$

and the complementary function is

$$y=F\epsilon^{\left\{-\frac{B}{2A}+\sqrt{\left(\frac{B^2}{4A^2}-\frac{C}{A}\right)}\right\}t}+F'\epsilon^{\left\{-\frac{B}{2A}-\sqrt{\left(\frac{B^2}{4A^2}-\frac{C}{A}\right)}\right\}t}$$

where F and F' are constants.

If $B^2>4AC$ the function increases or decreases exponentially, but there are no oscillations.

If $B^2<4AC$, the above solution is equivalent to

$$y=\epsilon^{-\frac{B}{2A}t}\left\{F''\cos\sqrt{\left(\frac{C}{A}-\frac{B^2}{4A^2}\right)}t+F'''\sin\sqrt{\left(\frac{C}{A}-\frac{B^2}{4A^2}\right)}t\right\}$$

and oscillations take place. These oscillations may be either damped or maintained.

If $B/2A>0$ they will be damped, and any disturbance set up will gradually die away; if, on the other hand, $B/2A<0$ oscillations are maintained, and, starting from any small disturbance, their amplitude increases until the original quantity $B/2A$ is balanced by the increase in damping which in general accompanies an increase in amplitude. At this moment the effective B is zero, and the equation of oscillations is

$$y=F''\cos\sqrt{\left(\frac{C}{A}\right)}t+F'''\sin\sqrt{\left(\frac{C}{A}\right)}t$$

The circular frequency ω is thus given by the equation

$$\omega^2=C/A$$

The final amplitude of y must be some function of the original value of $-B/2A$; it is not easy to estimate this function, in general, but in some cases the initial value of $-B/2A$ may be used to predict the final amplitude.

The following rules for the study of oscillations can thus be stated:

(i) If the coefficients of D^2 and D^0 are opposite in sign, no oscillations can take place.

(ii) If the coefficients of D^2 and D are of the same sign, no oscillations can be maintained.

(iii) If the coefficients of D^2 and D^0 are of the same sign, and opposite in sign to that of D, and if $4AC$ is greater than B^2, oscillations will be maintained at a frequency eventually given by $(1/2\pi)\sqrt{(C/A)}$.

(iv) The original value of $-B/2A$ may, in some cases, afford a means of calculating the final amplitude.

PLATE-TO-GRID CONNECTION.

Returning now to the particular problem of the quartz oscillator, suppose that the quartz resonator is connected between the grid and the plate of the valve. In this case

$$G_1=\left\{1/(DL+R)\right\}+DC+g_1 \quad . \quad . \quad . \quad . \quad (8)$$

$$G_2=g_2+g_4+DC_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

$$G_3=g_3+D(C_3+K_3)+D(K_1K_2/K_t)\,(\sigma/\nu) \quad . \quad (10)$$

The conductance of the grid leak is denoted by g_4. As for g_2 and g_3, they include not only the direct-current conductance of the glass and valve-holder, which is usually extremely small, but also the effective conductance due to dielectric loss in the glass and holder between the electrodes and the thermionic effect, if any. The direct-current component and the dielectric component of g_3 are different in their effects, which will be discussed later in the paper.

Substituting for G_1, G_2 and G_3 in equation (3), the following equation is obtained:—

$$\begin{aligned}&\left[D(K_1K_2/K_t)(\sigma/\nu)+g_3+D(C_3+K_3)\right]\\&\qquad\left[g_1+g_2+g_4+(m+1)g+D(C+C_2)+1/(DL+R)\right]\\&\qquad\quad+\left[g_2+g_4+DC_2\right]\\&\qquad\qquad\left[g_1+g+DC+1/(DL+R)\right]=0 \quad . \quad . \quad (11)\end{aligned}$$

The quantity operated on is y, standing for i_1, i_2, v or c, and will not be repeated each time.

For brevity, we can write

$$C_2+C_3+K_3=C_5 \quad . \quad . \quad . \quad . \quad (12)$$

Equation (11) can be put in the form

$$(K_1K_2/K_t)\,(\sigma/\nu)a+C_5=0 \quad . \quad . \quad (13)$$

in which a is a fraction whose numerator and denominator are both of the third degree in D.

The numerator of a will be

$$\begin{aligned} &D^3L(C+C_2) \\ &\quad + D^2\left[R(C+C_2)+\left\{g_1+g_2+g_4+(m+1)g\right\}L\right] \\ &\qquad + D\left[1+\left\{g_1+g_2+g_4+(m+1)g\right\}R\right] \quad . \quad (14) \end{aligned}$$

and the denominator will be a similar expression, with a term independent of D.

The evaluation of a is greatly simplified by neglecting mRg in comparison with unity. This can be done only when G_1 is an oscillatory circuit. The case when it is made up of a high resistance should be treated separately, and is simpler.

If the frequency were, say, 100 000 cycles per sec., and a low-impedance valve were used, the quantities considered might be as follows:

$$\begin{aligned} L &= 2\,000 \text{ microhenrys} \\ R &= 10 \text{ ohms} \\ m &= 10 \\ g &= 0{\cdot}0003 \text{ mho} \end{aligned}$$

Then $mRg = 0{\cdot}03$.

This is, however, an extreme case. It will be proved later that the resistance R of the coil L should be as small as possible if large powers are to be obtained. Moreover, quartz oscillators are in general worked at frequencies well above 100 000 cycles per sec. The value of mRg is, therefore, in most cases well under 0·01 and can be neglected in comparison with unity.

From equations (6), (7) and (13) we obtain

$$\begin{aligned} &\left\{D^2NK+DSK+1+(K/K_1)\right\}(K_1K_2/K_t)a \\ &\qquad + (D^2NK+DSK+1+K/K_t)C_5 = 0 \end{aligned}$$

$$\therefore\ D^2NK+DSK+1+\frac{K}{K_t}\cdot\frac{aK_2+C_5}{a(K_1K_2/K_t)+C_5}=0 \quad (15)$$

For brevity, we can write

$$1+\frac{K}{K_t}\frac{aK_2+C_5}{a(K_1K_2/K_t)+C_5}=\beta \quad . \quad . \quad (16)$$

The equation of oscillations is then

$$D^2NK+DSK+\beta=0 \quad . \quad . \quad . \quad (17)$$

and β can be put into the form

$$\frac{\phi_1(D^2)+D\phi_2(D^2)}{\phi_3(D^2)}$$

If it were possible to obtain an approximation for D^2, the equation would take the simple form

$$D^2NK+DSK+D\beta_2+\beta_1=0 \quad . \quad . \quad (18)$$

where β_1 and β_2 are real functions of the variables of the circuits.

When oscillations are just on the point of starting, or when oscillations are being maintained at a constant amplitude, the damping term is zero, that is

$$\beta_2+SK=0 \quad . \quad . \quad . \quad . \quad (19)$$

Therefore, also,

$$D^2NK+\beta_1=0 \quad . \quad . \quad . \quad . \quad (20)$$

The latter equation gives the required approximation for D^2.

It is here convenient to define a frequency f_0 by the formulæ

$$\left.\begin{aligned} \omega_0 &= 2\pi f_0 \\ \omega_0^2NK &= 1 \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad (21)$$

The frequency f_0 is that frequency at which the quartz vibrates when it is used as a resonator with no air-gap.

Having thus defined ω_0, let C_0 be a capacity determined by the relation

$$\omega_0^2LC_0=1 \quad . \quad . \quad . \quad . \quad . \quad (22)$$

The capacity C_0 will be that value of C, including the inter-electrode plate-to-filament capacity C_1, for which the natural frequency of the oscillatory circuit is equal to the natural frequency of vibration of the piece of quartz, used as a resonator with no air-gap.

Having written $\quad \beta=\beta_1+D\beta_2$

we can write $\quad a=a_1+Da_2$

where a_1 and a_2 are also real functions of the circuit variables.

Equation (20) gives

$$D^2=-\omega_0^2\beta_1 \quad . \quad . \quad . \quad . \quad . \quad (23)$$

Substituting this in the expression for a as derived from equation (11), we find that the numerator of a is $G+DH$, where

$$G=C+C_2-(C_0/\beta_1) \quad . \quad . \quad . \quad (24)$$

and

$$H=-(C_0/\beta_1)\left[R(C+C_2)+\left\{g_1+g_2+g_4+(m+1)g\right\}L\right] \quad (25)$$

If we write

$$U=C-(C_0/\beta_1) \quad . \quad . \quad . \quad . \quad (26)$$

and $\quad W=-(C_0/\beta_1)\left[RC+(g_1+g)L\right] \quad . \quad . \quad (27)$

we find that the denominator of a is $E+DF$, where

$$E=\frac{C_3+K_3}{C_5}G+\frac{C_2}{C_5}U+g_3\frac{H}{C_5}+(g_2+g_4)\frac{W}{C_5}$$

and

$$F=\frac{C_3+K_3}{C_5}H+\frac{C_2}{C_5}W-\frac{1}{\omega_0^2\beta_1}g_3\frac{G}{C_5}-\frac{1}{\omega_0^2\beta_1}(g_2+g_4)\frac{U}{C_5}$$

Finally, since

$$a=\frac{G+DH}{E+DF} \quad . \quad . \quad . \quad . \quad . \quad (28)$$

we have

$$a_1=\frac{GE+\omega_0^2HF\beta_1}{E^2+\omega_0^2F^2\beta_1} \quad . \quad . \quad . \quad (29)$$

and

$$a_2=\frac{HE-GF}{E^2+\omega_0^2F^2\beta_1}$$

$$HE-GF=-\frac{C_2}{C_5}\frac{mg}{\omega_0^2\beta_1}\left[C-\frac{C_0}{\beta_1}-\frac{C_2}{m}\left(1+\frac{R}{g}\frac{C_0}{L}\frac{1}{\beta_1}\right)\right]+\frac{1}{\omega_0^2\beta_1C_5}\left[g_1C_2^2+g_3(\omega_0^2H^2\beta_1+G^2)+(g_2+g_4)(\omega_0^2WH\beta_1+U^2)\right] \quad . \quad (30)$$

The expressions for E and F are

$$E = C + C_2 - \frac{C_2^2}{C_5} - \frac{C_0}{\beta_1} + g_3\frac{H}{C_5} + (g_2 + g_4)\frac{W}{C_5} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (31)$$

$$F = -\frac{C_0}{\beta_1}\left[R\left(C+C_2-\frac{C_2^2}{C_5}\right)+\left(m\frac{C_3+K_3}{C_5}+1\right)gL+g_1L+\frac{C+C_2-(C_0/\beta_1)}{C_5}g_3L+\frac{C+C_3+K_3-(C_0/\beta_1)}{C_5}(g_2+g_4)L\right] \quad . \qquad (32)$$

The expressions for β_1 and β_2 in terms of a_1 and a_2 can be obtained from equation (16). They are

$$\beta_1 = 1 + \frac{K}{K_t}\,\frac{(a_1K_2 + C_5)\left\{a_1(K_1K_2/K_t) + C_5\right\} + a_2^2\omega_0^2\beta_1(K_1K_2^2/K_t)}{\left\{a_1(K_1K_2/K_t) + C_5\right\}^2 + a_2^2\omega_0^2\beta_1(K_1K_2/K_t)^2} \quad . \quad . \quad . \quad . \quad . \quad . \qquad (33)$$

$$\beta_2 = \frac{a_2C_5(K_2/K_t)^2}{\left\{a_1(K_1K_2/K_t) + C_5\right\}^2 + a_2^2\omega_0^2\beta_1(K_1K_2/K_t)^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (34)$$

When oscillations are just on the point of starting, or are being maintained at a constant amplitude, $\beta_2 + SK = 0$, and therefore β_2 is negative, and of the same order of magnitude as SK. Equation (34) shows that a_2 must be negative when β_2 is negative.

When
$$a_2 < 0$$
$$GF > HE$$
$$G > \frac{HE}{F}$$

Hence
$$a_1 = \frac{GE + \omega_0^2HF}{E^2 + \omega_0^2F^2} > \frac{H}{F}$$

Moreover, since $a_2 < 0$, equation (30) shows that $C > C_0/\beta_1$.

Under these conditions, it is easily seen from equations (25) and (32) that H/F is positive, that is, greater than zero; hence a_1 is also greater than zero, and $a_1(K_1K_2/K_t) + C_5$ is of the same order of magnitude as C_5.

Equation (34) gives two negative roots for a_2 in terms of β_2. Since K/K_t is small, β_1 does not differ greatly from $1 + (K/K_t)$, that is, from unity, whatever be the value of a_2. The order of magnitude of one root of a_2 is therefore small and equal to SC_5. The second root is large, and its order of magnitude is $1/(\omega_0^2SK_1)$. This second root must, however, be rejected, for equations (29) and (30) show that the numerical value of a_2 is, except in some cases, over a very small range of values of C, less than $1/(\omega_0^2SK_1)$.

Since a_2 is small, we may write

$$\beta_1 = 1 + \frac{K}{K_t}\cdot\frac{a_1K_2 + C_5}{a_1(K_1K_2/K_t) + C_5} \quad . \quad . \qquad (35)$$

and
$$\beta_2 = \frac{a_2C_5K}{\left\{a_1(K_1K_2/K_t) + C_5\right\}^2}\cdot\frac{K_2^2}{K_t^2} \quad . \quad . \qquad (36)$$

If the capacity C be of such a value that $\beta_2 + SK < 0$, oscillations start and build up. As the amplitude of the oscillations increases, the modulus $|\beta_2 + SK|$ decreases, and therefore $|\beta_2|$ becomes more and more nearly equal to SK. The change in β_2 can be produced only by a change in the anode conductance g. Finally the amplitude of oscillations reaches such a value that the corresponding mean value of g makes the expression $\beta_2 + SK$ equal to zero. The amplitude ceases to increase, and the oscillations are maintained at constant amplitude.

The frequency of the oscillations depends upon β_1, and therefore upon a_1. This quantity changes with g, so that the frequency of the oscillations changes slightly during the process of building up. The time taken for this building up is, in general, of the order of 1 or 2 seconds.

The frequency with which we are concerned is, of course, the frequency corresponding to the constant amplitude. When the amplitude has reached its constant value, $\beta_2 + SK = 0$ and the order of magnitude of a_2 is SC_5. This being very small, and the denominator $E^2 + \omega_0^2F^2$ of a_2 being very small, it is necessary that the numerator $HE - GF$ should be very small, namely, of the order of $SC_5C_0^2$. When the amplitude has reached a constant value, it is, therefore, permissible to write

$$a_1 = \frac{G}{E} = \frac{H}{F} = \frac{C + C_2 - (C_0/\beta_1)}{C + C_2 - \dfrac{C_2^2}{C_5} - \dfrac{C_0}{\beta_1} - (g_2 + g_4)\left[\dfrac{C_0}{C_5\beta_1}(RC + gL)\right] - g_3\left[\dfrac{C_0}{C_5\beta_1}\left\{R(C + C_2) + (m + 1)gL\right\}\right]} \quad . \qquad (37)$$

This approximation will give a reasonably accurate value for the frequency. The effect of g_2, g_3, g_4 and R on the frequency will be considered later. It will be sufficient here to neglect the terms in g_2, g_3 and g_4, and to write

$$a_1 = \frac{C + C_2 - C_0/\beta_1}{C + C_2 - (C_2^2/C_5) - (C_0/\beta_1)} \quad . \qquad (38)$$

For brevity, we shall write a and β instead of a_1 and β_1.

The frequency of oscillations is given by

$$\omega^2 = \omega_0^2\beta$$

and, since β never departs much from unity,

$$f = f_0(\tfrac{1}{2} + \tfrac{1}{2}\beta) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (39)$$

The ratio of the coefficient of D to that of D^2 is

$$SK\omega_0^2 + \beta_2\omega_0^2 = SK\omega_0^2 + K\left(\frac{K_2}{K_t}\right)^2 \frac{g_1C_2^2 + g_3(\omega_0^2H^2 + G^2) + (g_2 + g_4)(\omega_0^2WH + U^2)}{E^2\left\{1 + (\omega_0^2F^2/E^2)\right\}\left\{\alpha(K_1K_2/K_t) + C_5\right\}^2}$$
$$- \frac{K(K_2/K_t)^2mgC_2\left[C - \frac{C_0}{\beta} - \frac{C_2}{m}\left(1 + \frac{R}{g}\frac{C_0}{L}\right)\right]}{E^2\left\{1 + (\omega_0^2F^2/E^2)\right\}\left\{\alpha(K_1K_2/K_t) + C_5\right\}^2} \quad . \quad . \quad . \quad (40)$$

This expression shows that S, g_1, g_2, g_3 and g_4 all tend to oppose the production of oscillations. It is also permissible to state that they tend to make the final amplitude smaller. In the case of the grid leak g_4 this rule, however, is not rigid, because the grid leak may alter the grid potential so as to cause oscillations to take place about a more favourable point on the characteristic curve of the valve.

If we substitute for α by equation (38), remembering that this is only an approximation which assumes $HE = GF$, we find for the ratio of the terms in D and D^2:—

It has been shown (p. 269) that $\alpha > 0$. Over the range

$$0 < \alpha < \infty$$

we have

$$\tfrac{1}{2}(K/K_t) < (\Delta f/f_0) < \tfrac{1}{2}(K/K_1)$$

Hence $(\Delta f/f_0)$ is always smaller than 1/280, which is the theoretical value of $\frac{1}{2}(K/K_1)$ for good quartz,* and is rarely reached in practice with resonators vibrating along the electric axes.

We have

$$\alpha = \frac{C + C_2 - (C_0/\beta)}{C + C_1 - (C_2^2/C_5) - (C_0/\beta)} \quad . \quad . \quad (45)$$

$$SK\omega_0^2 + K\left(\frac{K_2}{K_t}\right)^2 \frac{g_1C^2 + g_3(\omega_0^2H^2 + G^2) + (g_2 + g_4)(\omega_0^2WH + U^2)}{\left(1 + \frac{\omega_0^2F^2}{E^2}\right)\left(\frac{K_1K_2}{K_t} + C_5\right)^2\left(C + C_2 - \frac{C_0}{\beta} - \frac{C_2^2}{(K_1K_2/K_t) + C_5}\right)^2}$$
$$- K\left(\frac{K_2}{K_t}\right)^2 \frac{mgC_2\left[C - \frac{C_0}{\beta} - \frac{C_2}{m}\left(1 + \frac{R}{g}\frac{C_0}{L}\right)\right]}{\left(1 + \frac{\omega_0^2F^2}{E^2}\right)\left(\frac{K_1K_2}{K_t} + C_5\right)^2\left(C + C_2 - \frac{C_0}{\beta} - \frac{C_2^2}{(K_1K_2/K_t) + C_5}\right)^2} \quad . \quad (41)$$

When C is gradually increased from zero, the expression is positive and there can be no oscillations. When C reaches the value

$$C = \frac{C_0}{\beta} + \frac{C_2}{m}\left(1 + \frac{R}{g}\frac{C_0}{L}\right)$$

the expression is still positive; a small increase in C, however, makes it zero; a further increase makes it negative, and oscillations start. As C is still further increased, the expression quickly reaches a minimum, then increases again, gradually, until a certain large value of C is attained for which it becomes zero. At this point the oscillations stop. It is easy to find this limit, because for large values of C, G and F are large compared with ω_0H and ω_0F. It is given by

$$(mgC_2/C - C_0) = g_2 + g_3 + g_4 + S\omega_0^2\left\{K_1 + C_5(K_t/K_2)\right\}^2 \quad (42)$$

The lower limit of C is given by

$$C > \frac{C_0}{\beta} + \frac{C_2}{m}\left(1 + \frac{R}{g}\frac{C_0}{L}\right) \quad . \quad . \quad . \quad (43)$$

Closer approximations to this lower limit, or "cut-off point," will be obtained in the Sections dealing with amplitude, pp. 273 and 274. Equation (41) will also be used to study the changes in amplitude with respect to C and to the other circuit variables.

Relation between frequency and total capacity in the oscillatory circuit.—It is convenient to work in frequency differences above f_0. The difference

$$\Delta f = f - f_0 = \tfrac{1}{2}f_0(\beta - 1)$$

$$\therefore \frac{\Delta f}{f_0} = \frac{1}{2}\frac{K}{K_t}\frac{\alpha K_2 + C_5}{\alpha(K_1K_2/K_t) + C_5} \quad . \quad . \quad (44)$$

The quantity β is itself a function of α. The rigid procedure would therefore be to choose various values of α, to calculate β, and then obtain C from equation (45) and Δf from equation (44). The limits of α corresponding to the limits of C are easily found, from equation (45), to be

$$\infty > C > \frac{C_0}{\beta} + \frac{C_2}{m}\left(1 + \frac{R}{g}\frac{C_0}{L}\right)$$

$$1 < \alpha < \frac{m + 1 + (R/g)\,(C_0/L)}{m(C_3 + K_2/C_5) + 1 + (RC_0/gL)} \quad . \quad (46)$$

In view, however, of the fact that $\beta - 1$ is small and does not change much, it is simpler to substitute at once for α in equation (45) and to evaluate $\Delta f/f_0$.

$$\frac{\Delta f}{f_0} = \frac{1}{2}\frac{K}{K_t}\frac{\left\{C + C_2 - (C_0/\beta)\right\}(K_2 + C_5) - C_2^2}{\left\{C + C_2 - (C_0/\beta)\right\}\left\{(K_1K_2/K_t) + C_5\right\} - C_2^2} \quad (47)$$

$$\frac{\partial}{\partial C}\left(\frac{\Delta f}{f_0}\right) = -\frac{1}{2}K\left(\frac{K_2}{K_t}\right)^2$$
$$\frac{C_2^2}{\left\{C + C_2 - (C_0/\beta)\right\}\left\{(K_1K_2/K_t) + C_5\right\} - C_2^2} \quad (48)$$

This is always negative, and it increases numerically as C decreases. It is zero when C is infinite.

When C is very large, the frequency is given very nearly by

$$\frac{\Delta f}{f_0} = \frac{1}{2}\frac{K}{K_t}\frac{K_2 + C_5}{(K_1K_2/K_t) + C_5} \quad . \quad . \quad . \quad (49)$$

---

* See Reference (6).

As C is decreased, the frequency increases gradually, and the rate of increase increases until the oscillations stop.

Relation between Frequency and the Various Resistances of the Circuits.—Equation (37) shows that the effect of g_2, g_3, g_4, g and R is to increase a, and therefore also to increase the frequency. This increase, moreover, becomes greater and greater as C approaches its lower limit.

Relation between Frequency and the Inter-electrode Capacities.—We have, from equation (47):—

$$\frac{\partial}{\partial C_2}\frac{\Delta f}{f_0} = -\frac{1}{2}K\left(\frac{K_2}{K_t}\right)^2 \frac{\{C-(C_0/\beta)\}^2}{[\{C+C_2-(C_0/\beta)\}\{(K_1K_2/K_t)+C_5\}-C_2^2]^2} \quad . \quad (50)$$

It is always negative, and $\left|\frac{\partial}{\partial C_2}\frac{\Delta f}{f_0}\right|$ decreases with C_2. In this respect, a large C_2 would be an advantage.

On the other hand, equation (48) shows that the greater C_2 becomes, the greater is $\left|\frac{\partial}{\partial C}\left(\frac{\Delta f}{f_0}\right)\right|$; from this point of view a large C_2 would be a disadvantage. The value of C_2 is, in general, more important in its relation to the amplitude of oscillations than in its effect on the frequency.

For the variation of frequency with respect to C_3 we find

$$\frac{\partial}{\partial C_3}\frac{\Delta f}{f_0} = -\frac{1}{2}K\left(\frac{K_2}{K_t}\right)^2 \frac{\{C+C_2-(C_0/\beta)\}^2}{[\{C+C_2-(C_0/\beta)\}\{(K_1K_2/K_t)+C_5\}-C_2^2]^2} \quad . \quad (51)$$

The frequency therefore decreases with C_3, and the larger C_3 becomes, the smaller is the modulus of the rate of decrease. Variation of K_3 has exactly the same effect.

Relation between Frequency and Air-gap.—The variation of frequency with variation of air-gap is a little more complicated than with an ordinary resonator, in which case it is given by

$$\Delta f/f_0 = \tfrac{1}{2}(K/K_t) \quad . \quad . \quad . \quad . \quad (52)$$

For the oscillator a straight line could, in theory, be obtained by plotting Δf against the right-hand term of equation (47). There would be a different graph for each value of C.

In view of the fact that, even in a resonator, the frequency changes are not governed by relation (52) above, there would be no point in carrying out the more complicated computation in the case of the oscillator.

Amplitude of Oscillations.—The amplitude is closely related to the shape of the characteristic curves of the valve. If general algebraical expressions for those characteristics were available, general expressions might be obtained for the amplitude, but the problem would present great difficulties. It is possible, however, to arrive at interesting qualitative results, by general considerations of the shape of the characteristics.

The amplitude is greatly dependent upon the capacity C. Consider a circuit like that shown in Fig. 4. The resistance of the coil is small in comparison with the anode resistance of the valve, and the mean potential at A is very nearly equal to the difference of potential V between the terminals of the battery. If the grid potential e be varied, at a frequency f, between the limits e_1 and e_2, the plate current will alternate between, say, i_1 and i_2, but will never, of course, be less than zero. If the impedance of the oscillatory circuit to current of frequency f be Z, the amplitude $v_1 - v_2$ of the alternations in potential at A will be equal to $Z(i_2 - i_1)$.

In a self-maintained oscillator, the amplitude of the oscillations, starting from a small disturbance, increases until the swing of grid potential is such that a further increase would not produce any increase in the amplitude of variation of the current.

The impedance Z of the oscillatory circuit is a maximum when C is adjusted so that $4\pi^2LCf^2$ is unity. The impedance is then equal to L/RC. Hence the amplitude is approximately inversely proportional to the resistance R of the oscillatory circuit. The law is not exact. The variations in voltage across Z are produced by variations in the plate current. The plate current is itself, however, a function of plate voltage. On the straight part of the characteristic curve of the valve,

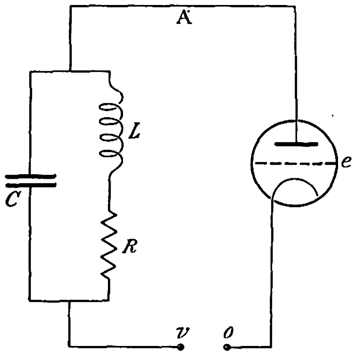

FIG. 4.

$$v_1 - v_2 = \frac{gZ}{1+gZ}m(e_2 - e_1)$$

It is nevertheless always true to say that the smaller R becomes, the greater is the amplitude V. The power, however, is not, in general, a maximum at this point; it is equal to $\frac{1}{2}RC^2\omega^2V^2$, and the "useful power" is zero.

If a resistance R' be added to R, the amplitude of the oscillations will be reduced to, say, V', and the total power will be $\frac{1}{2}(R + R')C^2\omega^2V'^2$. This may, or may not, be greater than $\frac{1}{2}RC^2\omega^2V^2$. The useful power is now $\frac{1}{2}R'C^2\omega^2V'^2$. In practice the increase of resistance R' is not produced by an actual resistance added to R; it is the effective increase of resistance due to the coupling between L and the circuit in which the power supplied by the quartz oscillator is being usefully employed.

In the case of the quartz oscillator, the simple relation $LC\omega^2 = 1$, that is, $C = C_0$, cannot be used to find the value of C for maximum amplitude, because of the presence of the inter-electrode capacities.

Suppose that, in a self-oscillatory valve circuit, the potential of the grid, before any oscillations start, is E_1 (Fig. 5). The corresponding point on the characteristic is A_1. When oscillations start, but the amplitude is still small enough, say E_2E_3, there is no change in the mean plate current. On the other hand, there is nothing to prevent the oscillations from building up, and the amplitude increases until, during part of the swing, the grid potential is positive. During this part of the swing, grid current flows and tends to lower the grid potential. During the rest of the cycle, there is no effect tending to increase the grid potential. In other words, there is a tendency for the swing of grid potential to be opposed on the positive side, but not on the negative side; as a consequence the mean grid potential falls to the left of E_1, say to E_4. The average plate current is not, in general, that corresponding to A_4, but to a point somewhere between A_4 and A_1. If, by some alteration in the valve circuits the amplitude is made to increase still more, and the maximum grid potential is, say, E_5, the effect due to grid current becomes still more pronounced, and the swing on the other side, namely, E_4E_6, is much greater than E_4E_5; the mean grid potential decreases further to E_7, and there is a fall in the average plate current, which now corresponds to some point A between A_7 and A_4. This decrease of plate current with amplitude is well exhibited by the experimental curves in Fig. 25. The rule does not hold quite as rigidly when the resistance in the oscillatory circuit is large, because in that case the maximum amplitude is small, and the swing of grid voltage towards the positive side does not exceed, say, E_8. It may then occur that the increase in average plate current with amplitude, due to the anode rectification, more than compensates for the decrease due to the lowering of mean grid potential, itself a result of the flow of grid current.

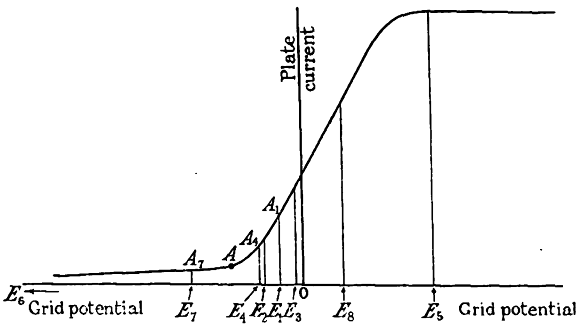

FIG. 5.

If we ignore this slight departure from the rule, we may state that the average plate current falls as the amplitude increases. Under those conditions, the average plate conductance g will also fall with increasing amplitude, as can best be seen by the shape of the plate-volts/grid-volts characteristics of a valve, for various plate currents.

Consider now expression (41), and suppose that the capacity is at first very large; no oscillations can take place because the expression is positive. The plate current is fixed solely by the plate, filament, and grid voltages. We may suppose, for the sake of argument, that there is a grid leak; the potential of the grid is then equal to the potential of the filament; denote the corresponding plate current and plate conductance by I_0 and g_0. Let C be decreased gradually. When it reaches the limit given by equation (42), expression (41) is just zero, and oscillations are on the point of starting. The value of g to be used in equation (42) is therefore g_0. Suppose C to be decreased further. If the value of g were still g_0, expression (41) would be negative. Oscillations therefore build up, and the amplitude increases, until g reaches the value such that expression (41) becomes equal to zero. This new value of g will depend upon the setting of C, and the amplitude will be some function of $1/g$. It might be possible to find the amplitude in terms of the average g from a complete set of characteristics, but the process would, undoubtedly, be complicated. It will, nevertheless, be interesting for us to plot the value of $1/g$ against C, and to compare the curve thus obtained with the amplitude curves obtained experimentally. The curves must not, of course, be expected to coincide. All that can be expected is that (d/dC) should have the same sign for both curves.

When the value of C is that given by equation (42), oscillations are just on the point of starting, the amplitude is zero, and the plate conductance is g_0. It is therefore convenient to plot $(1/g) - (1/g_0)$, or $r - r_0$, against C, where r, the reciprocal of g, is the mean internal plate resistance of the valve.

The effect of some of the circuit variables on the amplitude can be predicted without actually plotting the curves.

The terms in S, g_1, g_2, g_3, g_4 and R, all tend to raise the value of g which makes expression (41) equal to zero. All the damping terms are, therefore, in general, detrimental. It may occur, however, that by a judicious choice of the grid leak g_4 the mean grid potential becomes such that oscillations take place about a more favourable point on the characteristic curve of the valve. Under these conditions the effect of g_4 would be beneficial.

The conductance g_3 between anode and filament may be considered as being made up of two parts: the first, g_3', a small direct-current conductance due to want of perfect insulation, and the second, g_3'', due to the dielectric losses in the glass and holder. This latter component, by far the larger of the two, merely increases the damping and slightly reduces the amplitude of oscillations; the component g_3' tends to equalize plate and grid potential, and therefore to stop the oscillations. It is, however, very small, being probably less than 10^{-8} mho in most valves.

The third term of expression (41) contains as a factor $C_2/\{K_1 + C_5(K_t/K_2)\}^2$.

When C_2 is zero, expression (41) will be positive, and no oscillations can take place. In the same way, large values of C_2 make the third term small numerically, and the expression will again be positive. There will therefore be, for each value of C, an optimum value of C_2.

The inter-electrode plate-to-grid capacity C_3, and the stray capacity K_3 in parallel with it, increase C_5, and therefore increase the term in S in expression (41). Their presence is, therefore, always detrimental; hence the use, by J. R. Harrison, of a screened plate, to do away with the capacity C_3. Hence also the importance of keeping as low as possible the stray capacity K_3 between the electrodes and leads of the resonator.

The term in S is multiplied by

$$\{K_1 + C_5(K_t/K_2)\}^2$$

The amplitude obtainable with a small air-gap will thus be larger than the amplitude with a large air-gap, because the smaller the air-gap the smaller is (K_t/K_2).

The value of g obtained by equating expression (41) to zero is independent of the initial value g_0, other things being equal. In a low-impedance valve, however, the swing of plate current required to produce a given change in the mean plate conductance is larger than in a high-impedance valve. Hence, the lower the normal plate impedance r_0, the greater will the amplitude be.

The third term in expression (41) contains the amplification constant m as a factor. The greater m, the smaller will be the value of g which makes the expression equal to zero; a large amplification factor is therefore beneficial, other things being the same.

The analysis of expression (41) is greatly simplified by supposing that

$$C_2 + C - \frac{C_0}{\beta} - \frac{C_2^2}{C_5}$$

and

$$C_2 + C - \frac{C_0}{\beta} - \frac{C_2^2}{(K_1K_2/K_t) + C_5}$$

are nearly equal. In numerical computation this supposition is not even necessary.

Writing, for brevity, $C - (C_0/\beta) = x$, we can put expression (41) into the form

$$\Sigma[(a_1x+a_2)^2+(a_3x+a_4g+a_5)^2]+a_6+a_7g-a_8gx \quad . \quad (53)$$

in which the coefficients a_1, . . . etc., are all positive. The Σ includes four similar terms, which contain, as factors, S, g_1, g_3, and $g_2 + g_4$ respectively; some of the coefficients a_1, a_2, . . . etc., may be zero. We see at once that there cannot be any maintained oscillations unless x be positive. The expression can then be put into the simpler form

$$\phi = x^2 + Ax + B + Cg^2 + Dg - Exg \quad . \quad (54)$$

where the coefficients A, B, C, D and E are all positive.

Since x is positive, oscillations cannot be maintained unless

$$Ex > D$$

This, however, is not the only condition, because some positive values of x might give imaginary roots for g in the equation $\phi = 0$. We therefore require the further condition

$$\phi_2 = (Ex - D)^2 - 4C(x^2 + Ax + B) \geqq 0 \quad . \quad (55)$$

Since Ex is positive and greater than D, this condition requires that

$$E^2 > 4C$$

Whenever the inequality (55) is satisfied, the two values of g given by the equation $\phi = 0$ are real. They are, moreover, both positive, since their sum and their product are positive.

The differential coefficient of ϕ_2 is

$$2E(Ex - D) - 4C(2x + A)$$

But we also have

$$(Ex - D)^2 - 4C(x^2 + Ax + B) \geqq 0$$
$$\therefore \quad Ex(Ex - D) - 4C(x^2 + Ax + B) > 0$$
$$2Ex(Ex - D) - 4C(2x^2 + 2Ax + 2B) > 0$$
$$2E(Ex - D) - 4C(2x + A) > 0$$

The differential coefficient of expression (55) is thus positive for all values of x over which oscillations may take place. Expression (55) therefore increases with x.

Denote by ξ_2 the larger of the two roots of the equation $\phi_2 = 0$. For the maximum amplitude, that is, for the minimum value of g with respect to x or C, we have the equations

$$\phi = 0 \quad \text{and} \quad dg/dx = 0$$

But

$$\frac{\partial\phi}{\partial x} + \frac{\partial\phi}{\partial g}\frac{dg}{dx} = 0$$

The condition for a minimum g is therefore

$$\left.\begin{aligned} \phi &= 0 \\ \partial\phi/\partial x &= 0 \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \quad (56)$$

The second of these equations is

$$2x + A - Eg = 0 \quad . \quad . \quad . \quad (57)$$

Substituting for g in the first, we find

$$(Ex - D)^2 - 4C(x^2 + Ax + B) = BE^2 + A^2C + ADE + D^2 - 4CB \quad (58)$$

But since $E^2 > 4C$, the right-hand term of expression (58) is always positive, and the value ξ_1 of x given by expression (58) is greater than ξ_2. The amplitude therefore reaches a maximum before the point of cut-off.

In general, the two equal values of g corresponding to ξ_2, namely $\dfrac{E\xi_2 - D}{2C}$, are smaller than g_0, and the corresponding value of r is larger than r_0. As soon as C is reduced to $\xi_2 + (C_0/\beta)$, oscillations stop suddenly. For this reason the value of C corresponding to ξ_2 will be called the "cut-off point." If the damping terms were large, ξ_2 would be large, and the corresponding value of r might be less than r_0. In such a case the curve of r against C would cut the line $r = r_0$ at some point ξ_3 between ξ_1 and ξ_2. If C were decreased gradually, the amplitude would rise to a maximum and then decrease gradually, and become zero at $C = (\xi_3 + C_0/\beta)$, but there would be no sudden cut-off.

Two other interesting points are obtained by substituting g_0 for g in equation (54) and solving for x.

Unless the damping terms be very large, Eg_0 is greater than A and there are two positive roots. If A were greater than Eg_0, no oscillations could ever start of themselves. It is easily seen by inspection that the smaller the damping terms, the smaller will be the product of the roots and the larger will be the difference between the roots. The smaller of the two roots, say ξ_4, is larger than ξ_2, since ξ_2 is the limiting value of C below which no real values of g can satisfy the equation $\phi = 0$. The second root ξ_5 corresponds to the limiting value of C above which no oscillations can take place. The above method gives this limit a little more accurately than the simpler formula (42).

For values of x greater than ξ_5 no oscillations can be started and maintained. When x is decreased gradually and reaches ξ_5, oscillations start; the amplitude is very small when x is only slightly less than ξ_5; as x is further decreased the amplitude increases and reaches a maximum at ξ_1, then decreases rather rapidly, and just past ξ_2 the oscillations stop suddenly. If x is then increased, oscillations cannot start at ξ_2; they only start after x has been further increased to ξ_4. If x is kept at ξ_4, the oscillations start, and the amplitude builds up in a very short time. It is easy to find the point g on the curve, corresponding to this amplitude, by substituting ξ_4 for x in equation (54), and solving for g. The sum of the roots is equal to $(E\xi_4 - D)/C$, and one of them is g_0. Moreover, since ξ_4 is small, the value of g_0 is itself not very different from the above sum when the damping terms A and B are small. The second root is therefore small in comparison with g_0, and corresponds to a fairly large amplitude.

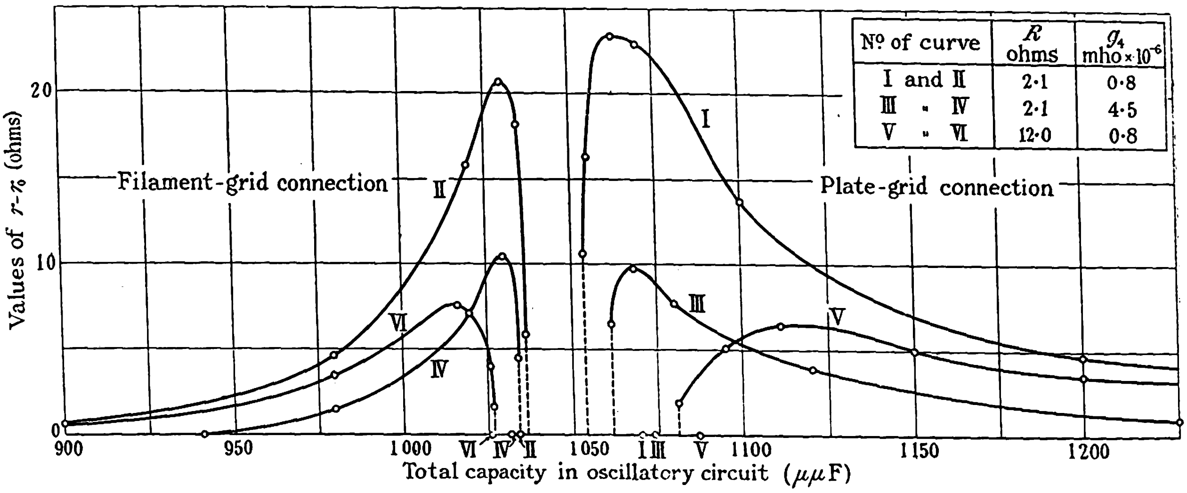

FIG. 6.—Curves of increase in mean plate resistance with variation of capacity in the oscillatory circuit. D.E.R. valve.

TABLE 1.

S = 400 ohms

For curves I, II, III and IV R = 2·1 ohms

For curves V and VI .. R = 12·0 ohms

K = 0·018 $\mu\mu$F

K_2 = 136 $\mu\mu$F

K_1 = 9·6 $\mu\mu$F

C_2 = 6·4 $\mu\mu$F

C_3 = 2·4 $\mu\mu$F

K_3 = 15·2 $\mu\mu$F

$C_2 + C_3 + K_3 = C_5$ = 24 $\mu\mu$F

C_0 = 1 043 $\mu\mu$F

C_0/β for plate-grid connection = 1 042·3 $\mu\mu$F

C_0/β for filament-grid connection = 1 042·5 $\mu\mu$F

L = 160·6 μH

g_1 = $0{\cdot}2 \times 10^{-6}$ mho

g_2 = $0{\cdot}5 \times 10^{-6}$ mho

g_3 = $0{\cdot}05 \times 10^{-6}$ mho

For curves I, II, V and VI g_4 = $0{\cdot}8 \times 10^{-6}$ mho

For curves III and IV .. g_4 = $4{\cdot}5 \times 10^{-6}$ mho

g_0 = 42×10^{-6} mho

m = 8·6

ω_0 = $2{\cdot}442 \times 10^6$ per sec.

Other points on the curves can be calculated by choosing particular values of x and solving for g.

This has been done in Fig. 6. The points marked (I), (III) and (V) on the axis of capacities are the points corresponding to ξ_4.

The values of the circuit variables used in the computation of the curves were obtained by direct measurements, to be described later, on the valve, the oscillatory circuits and the quartz resonator. The measurements were quite independent of any experimental results obtained by using the quartz as an oscillator.

The values adopted are given in Table 1. Curves II, IV and VI refer to the grid-to-filament connection.

The shape of these theoretical curves will be compared with that of the experimental curves in a later Section of the paper.

FILAMENT-TO-GRID CONNECTION.

The case in which the electrodes of the quartz resonator are connected to the grid and to the filament of the valve will be treated very briefly, for the procedure is analogous to that adopted in the previous case.

We have

$$G_1 = DC + \left\{1/(R + DL)\right\} + g_1 \quad . \quad . \quad . \quad . \quad . \quad (59)$$

$$G_2 = g_2 + g_4 + D(C_2 + K_3) + D(K_1K_2/K_t)(\sigma/\nu) \quad (60)$$

$$G_3 = g_3 + DC_3 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (61)$$

and substituting in equation (3) it is seen that the resulting equation is identical with equation (11) after interchanging

$g_2 + g_4$ and g_3

C_2 and C_3

$(m + 1)g$ and g

We then find:

$$G' = (C_0/\beta) - C - C_3 \quad \ldots \quad (62)$$

$$H' = (C_0/\beta)\left[R(C + C_3) + L(g + g_1 + g_3)\right] \quad \ldots \quad (63)$$

$$U' = (C_0/\beta) - C \quad \ldots \quad (64)$$

$$W' = (C_0/\beta)\left[RC + L(g_1 + (m + 1)g)\right] \quad \ldots \quad (65)$$

$$E' = (C_0/\beta) - C - C_3 + (C_3^2/C_5) + (g_2 + g_4)(H'/C_5) + g_3(W'/C_5) \quad \ldots \quad (66)$$

$$F' = \frac{C_2 + K_3}{C_5}H' + \frac{C_3}{C_5}W' - \frac{1}{\omega_0^2\beta C_5}\left[(g_2 + g_4)G' + g_3U'\right] \quad \ldots \quad (67)$$

$$a = \frac{(C_0/\beta) - C - C_3}{(C_0/\beta) - C - C_3 + (C_3^2/C_5) + (g_2 + g_4)(H'/C_5) + g_3(W'/C_5)} \quad \ldots \quad (68)$$

$$= \frac{1}{2}\frac{K}{K_t}\frac{aK_2 + C_5}{a(K_1K_2/K_t) + C_5} \quad \ldots \quad (69)$$

$$= \frac{1}{2}\frac{K}{K_t}\frac{\left\{(C_0/\beta) - C - C_3\right\}(K_2 + C_5) + C_3^2}{\left\{(C_0/\beta) - C - C_3\right\}\left\{(K_1K_2/K_t) + C_5\right\} + C_3^2} \quad \ldots \quad (70)$$

The ratio of the coefficient of D to that of D^2 is

$$SK\omega_0^2 + K\left(\frac{K_2}{K_t}\right)^2\frac{g_1C_3^2 + (g_2 + g_4)(G'^2 + \omega_0H'^2) + g_3(U'^2 + \omega_0^2W'H')}{\left(\frac{K_1K_2}{K_t} + C_5\right)^2\left(1 + \frac{\omega_0^2F'^2}{E'^2}\right)\left(\frac{C_0}{\beta} - C - C_3 + \frac{C_3^2}{(K_1K_2/K_t) + C_5}\right)}$$

$$- K\left(\frac{K_2}{K_t}\right)^2\frac{mgC_3\left[\frac{C_0}{\beta} - C_3 - \frac{C_3}{m}\left(1 + \frac{R}{g}\frac{C_0}{L}\right) - C\right]}{\left(\frac{K_1K_2}{K_t} + C_5\right)^2\left(1 + \frac{\omega_0^2F'^2}{E'^2}\right)\left(\frac{C_0}{\beta} - C - C_3 + \frac{C_3^2}{(K_1K_2/K_t) + C_5}\right)^2} \quad . \quad (71)$$

For maintenance of oscillations, we must have the inequality

$$\frac{C_0}{\beta} > C + C_3 + \frac{C_3}{m}\left(1 + \frac{R}{g}\frac{C_0}{L}\right) \quad . \quad . \quad (72)$$

The corresponding value of a is

$$\frac{1 + \frac{R}{g}\frac{C_0}{L}}{m\frac{C_3}{C_5} + 1 + \frac{R}{g}\frac{C_0}{L}}$$

The value of C below which oscillations cannot be maintained is given by

$$\frac{mgC_3}{C_0 - C} = g_2 + g_3 + g_4 + S\omega_0^2\left(K_1 + \frac{C_5K_t}{K_2}\right)^2 \quad . \quad (73)$$

Hence the total range of capacity C over which oscillations are possible with the grid-to-filament connection is to the corresponding range in the plate-to-grid connection as C_3 is to C_2. The value of a corresponding to formula (73) is very nearly unity, but never reaches unity.

Relation between Frequency and Total Capacity in the Oscillatory Circuit.—We have

$$\frac{\partial}{\partial C}\frac{\Delta f}{f_0} = -\frac{1}{2}K\left(\frac{K_2}{K_t}\right)^2\frac{C_3^2}{\left[\left\{(C_0/\beta) - C - C_3\right\}\left\{(K_1K_2/K_t) + C_5\right\} + C_3^2\right]^2} \quad \ldots \quad (74)$$

This shows that, all over the range, the frequency decreases as C increases. Moreover, the rate of decrease increases with C and becomes very large when C approaches the cut-off point.

The asymptotic frequency, corresponding to the small values of C, is given by

$$\frac{\Delta f}{f_0} = \frac{1}{2}\frac{K}{K_t}\frac{K_2 + C_5}{(K_1K_2/K_t) + C_5}$$

just as in the case of the plate-to-grid connection. The frequency lies entirely below this asymptotic frequency, and is therefore always less than the frequency for the plate-to-grid connection, but it is never as low as the response frequency of the resonator used as such, given by

$$\frac{\Delta f}{f_0} = \frac{1}{2}\frac{K}{K_t}$$

Since a is positive and finite, whichever be the type of connection of the resonator to the valve, the maximum variation of $(\Delta f/f_0)$ is less than $\frac{1}{2}(K/K_1)$, which is only a small fraction of the frequency.

Relation between Frequency and the Various Resistances of the Circuits.—Expression (68) shows that the effect of g_2, g_3, g_4, g and R is to decrease a, and therefore to decrease the frequency. This decrease is, moreover, greater and greater as C approaches its upper limit.

Relation between Frequency and the Inter-electrode Capacities.—We have, from equation (70),

$$\frac{\partial}{\partial C_3}\frac{\Delta f}{f_0} = -\frac{1}{2}K\left(\frac{K_2}{K_t}\right)^2 \frac{\left\{(C_0/\beta) - C\right\}^2}{\left[\left\{(C_0/\beta) - C - C_3\right\}\left\{(K_1K_2/K_t) + C_5\right\} + C_2^2\right]^2} \quad . \quad . \quad . \quad . \quad . \quad (75)$$

This is always negative, and therefore the frequency decreases with increase of C_3.

Similarly, we have

$$\frac{\partial}{\partial C_2}\frac{\Delta f}{f_0} = -\frac{1}{2}K\left(\frac{K_2}{K_t}\right)^2 \frac{\left\{(C_0/\beta) - C - C_3\right\}^2}{\left[\left\{(C_0/\beta) - C - C_3\right\}\left\{(K_1K_2/K_t) + C_5\right\} + C_3^2\right]^2} \quad . \quad . \quad . \quad . \quad . \quad (76)$$

which shows that the frequency decreases with increase of C_2, but that the rate of decrease decreases.

Amplitude of Oscillations.—Expression (71) shows that, when C_3 is zero or infinite, no oscillations can take place. There is, therefore, for each value of C, a particular optimum value of C_3 which makes g a minimum when expression (71) is equated to zero and solved for g.

The capacity $C_2 + K_3$, in parallel with the quartz resonator, is always detrimental.

Curves II, IV and VI in Fig. 6 show the excess mean internal resistance, $r - r_0$, for various values of C.

When C is very small—it can never be zero, because it includes the inter-electrode capacity C_1 and the self-capacity of the coil L—there may or may not be oscillations, depending upon whether C is above or below the limiting value given by equation (73). When C is increased past this value, oscillations start at a very small amplitude, which increases slowly at first, then more rapidly, until it reaches a maximum. Past this point the amplitude decreases very rapidly, until a certain value of C is reached at which the oscillations stop suddenly. The capacity at cut-off is very near to the capacity for a maximum, especially if the damping terms, that is, the terms containing S, g_1, g_2, g_3, g_4 and R, are small.

(2) EXPERIMENTAL INVESTIGATION.

DESCRIPTION AND BEHAVIOUR OF THE QUARTZ DISC.

Only one piece of quartz was used throughout the experiments. It was a disc 4·85 cm in diameter and 0·752 cm thick. The electric axis was perpendicular to the plane of the disc, and the only mode of vibration studied was that which took place along the electric axis.

According to Hund's empirical formula, the frequency should have been equal to 287/0·752, or 382 kilocycles per sec.

The piece of quartz, however, gave two strong responses at frequencies of approximately 389 and 385 kilocycles per sec. respectively. Besides these, there were several weak responses at frequencies not very different from the above.

The response at 389 kilocycles per sec. was a little stronger than that at 385. When the quartz electrodes were connected to the grid and plate of the valve, oscillations were, in general, maintained only at 389 kilocycles per sec.; when the filament-to-grid connection was used, and the capacity in the oscillatory circuit was very small, no oscillations were maintained. As the capacity was gradually increased, oscillations started, and their amplitude gradually increased to a maximum; the frequency of these oscillations was approximately 389 kilocycles per sec. A further slight increase in the capacity would alter the circuit conditions, and the oscillations stopped. At this point the quartz started oscillating in the other mode and, as the capacity was further increased, the amplitude increased, and then decreased almost abruptly to zero at the value of capacity for which the circuit conditions for the maintenance of oscillations at 385 kilocycles per sec. were no longer fulfilled. The difference between the two limiting capacities was, of course, approximately equal to (2 × 4)/390, or 2 per cent of the total capacity.

Under certain conditions it was possible to obtain the two oscillations simultaneously: an audible note of approximately 4 000 cycles per sec. was then produced.

AIR-GAP AND ELECTRODES.

For the air-gap and electrodes use was made of an apparatus designed by Dr. Dye for the interferometric examination of vibrating quartz plates. The apparatus as used for the present purpose is shown in Fig. 7. The quartz disc Q rests by its own weight upon a brass electrode D, which, in turn, is supported upon three small steel balls (by hole, slot and plane location) upon the main base-plate B. The base-plate carries 3 well-fitted levelling screws S with ball ends and knurled ebonite heads. Each screw is fitted with a graduated circle C. The pitch of the screw is ½ mm, and the circumference of the circle is divided into 50 equal parts, of which a tenth part can be estimated without much difficulty. This is equivalent to 0·0001 cm. The position of the circle is read by means of the index I, fixed to the base-plate. The screws support a glass plate P, of which the lower surface is plane polished. To this lower surface are wrung 4 polished brass discs, 3 of which, H, rest directly on the screws; the fourth, L, constitutes the upper electrode; its diameter exceeds that of the quartz disc by 2 mm. To this disc is soldered

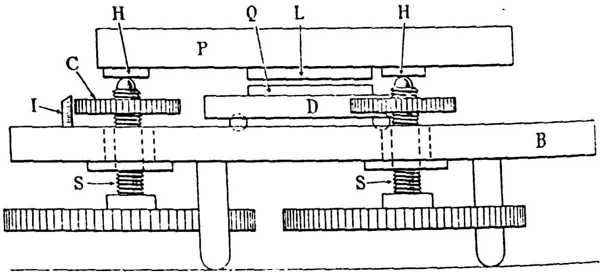

FIG. 7.

a thin copper wire which connects it to a terminal of the apparatus; the second terminal is in electrical connection with the base-plate. When the quartz is used as a resonator, the insulated terminal of the main condenser is connected to the disc, because the capacity to earth of the disc is much smaller than the capacity to earth of the base-plate. For the same reason the disc is always connected to the grid when the quartz is used with a valve.

In order to obtain the screw readings for zero air-gap, the discs H are connected together and to one terminal of a telephone. The base-plate is connected to the other terminal of the telephone through a source of alternating current of audible frequency. The 3 screws are lowered until the ball ends are out of contact with the discs H. The upper electrode L is then resting on the upper face of the quartz, and the air-gap is zero. Each of the screws is adjusted until the slightest further upward motion would bring them into contact with the discs H, and the position of the circles is noted. Contact is, of course, indicated by the telephone.

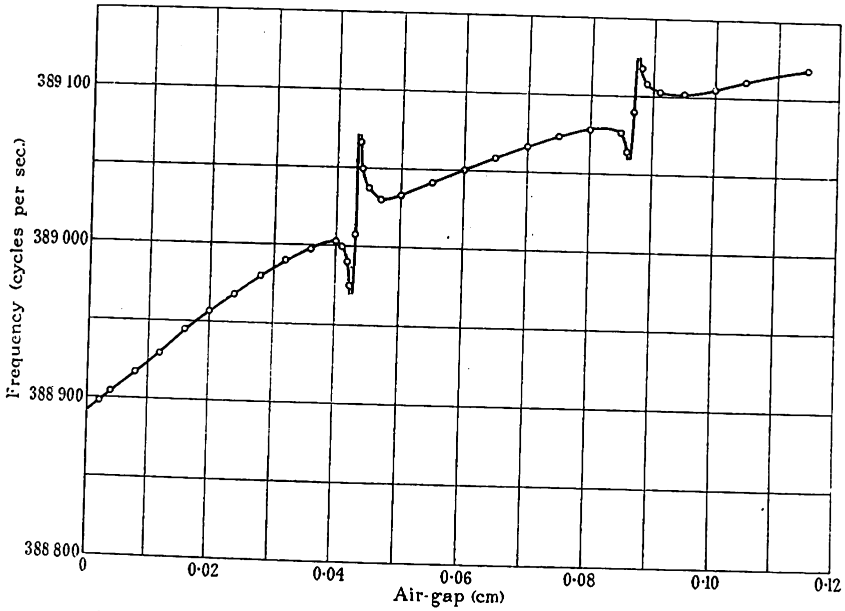

FIG. 8.—Response frequency of the resonator at various air-gaps.

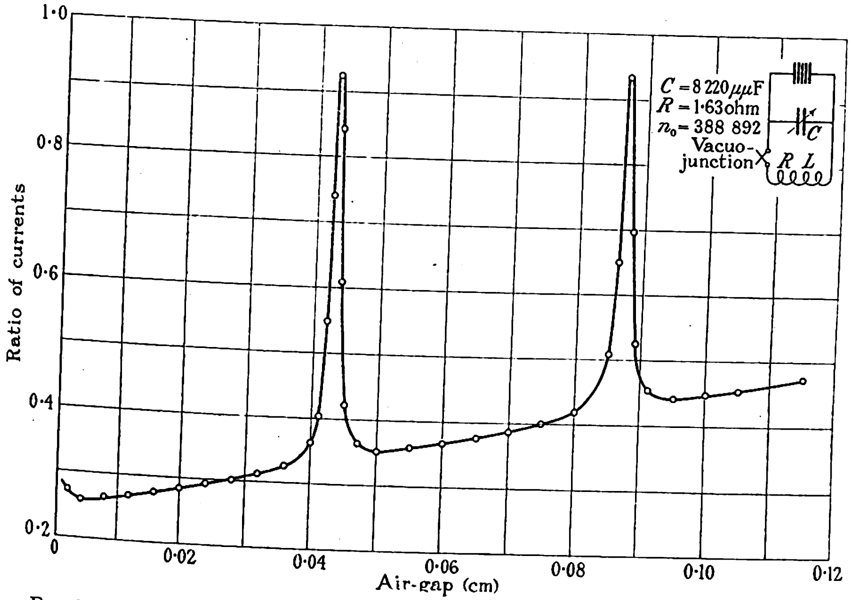

FIG. 9.—Ratio of minimum current to current when the quartz is not vibrating.

ELECTRICAL CONSTANTS OF THE QUARTZ.

The constants were measured by Dye's method. The quartz electrodes are connected to the terminals of the condenser of an oscillatory circuit, and the inductance coil of the circuit is loosely coupled to a source of alternating power at approximately the quartz frequency. The frequency is varied and the current in the oscillatory circuit is measured by means of a thermo-junction placed in series with the inductance coil. The reader who desires more information on this method should consult Dye's paper.*

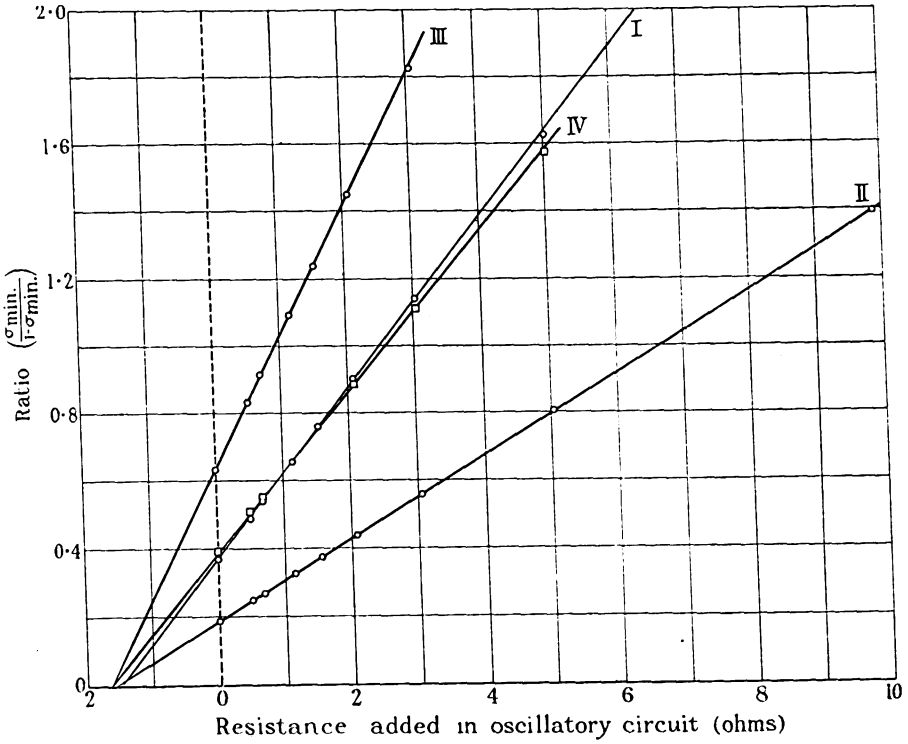

FIG. 10.—Determination of resistances of the circuits of the resonator.

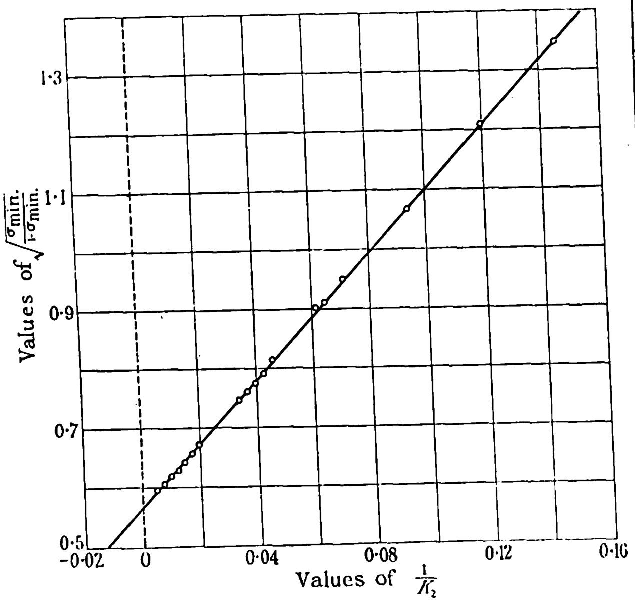

FIG. 11.—Determination of K_1, and of S, the damping of the resonator.

This method of analysis necessitates a variation of air-gap and a knowledge of the corresponding capacity K_2. This capacity is calculated by the formula $S/3\cdot6\,\pi g$ micro-microfarads, where S is the area of the surface of the quartz, and g the length of the air-gap in cm. With the dimensions given above, $K_2 = 1\cdot633/g$ micro-microfarads.

Fig. 8 shows the frequency for various air-gaps, and Fig. 9 the corresponding value of the minimum current in the inductance coil. The large increase of damping at air-gaps of 0·043 cm and 0·087 cm is due to the resonance of the air in the gap. The corresponding velocity of propagation of the waves is 34 200 cm per sec. The average room temperature was 16·5° C.

Fig. 10 gives the resistances of the two circuits used. The capacities of the two circuits were obtained by direct reading of the condensers. Fig. 11 gives $K_1 = 9\cdot6\ \mu\mu$F, and also the damping S of the quartz.

This damping S depends upon the mode of support of the quartz and upon the atmospheric conditions. It is therefore necessary to measure it anew whenever experiments are being carried out on the quartz. Once K_1 has been obtained, S can be calculated from a measurement of the minimum current for a single value of the air-gap K_2. The value of S varied between 350 and 500 ohms.

Resonance curves like Fig. 12 were obtained for four different air-gaps. They give the value of $f_2 = SK\omega$, and, since S can be obtained from the minimum σ as explained above, the value of K is found. This is equal to 0·018 $\mu\mu$F.

The graph of frequency against $1/(K_1 + K_2)$ should, according to the formulæ, be a straight line, and would give a means of checking the value of K. In practice, however, this graph is not a straight line, as Fig. 13 shows. This want of agreement occurs in all resonators, and deserves careful consideration. We cannot, however, dwell upon this point here, because we are mainly concerned with quartz oscillators.

---

* See Reference (4).

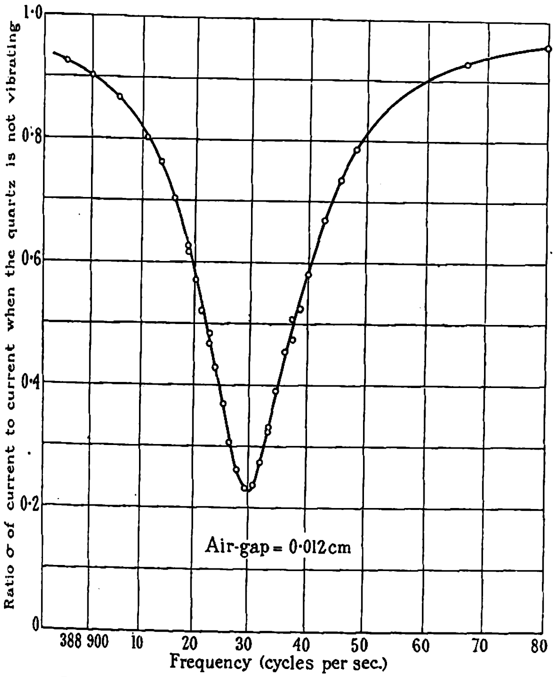

FIG. 12.—Resonance curve of the resonator.

The ratio of K_1 to K is 530, instead of the theoretical value 140. The value of K_1, calculated from a permittivity of 4·55, is 9·9, which does not differ much from the experimental figure 9·6 found above.

The investigation on the quartz used as an oscillator, in connection with a valve, was carried out for only one value of the air-gap, namely 0·012 cm. The corresponding value of K_2 is 136 $\mu\mu$F, and the value of (K_2/K_t) is 0·935.

The stray capacity K_3 between the two electrodes and their leads was deduced from measurements of the total capacity between the ends of those leads for various frequencies on each side of the resonance frequency. The value was 15 $\mu\mu$F.

The curve in Fig. 12 gives the response frequency of the resonator at an air-gap of 0·012 cm and a room temperature of 20·5° C. It is 388 930 cycles per sec. All the frequencies given in this paper have been reduced to the same room temperature, namely 20·5° C.

Fig. 8 also gives f_0, the response frequency for zero air-gap; it is 388 892 cycles per sec.

If the frequency at an air-gap of 0·012 cm were calculated from f_0 by the formula

$$f - f_0 = (f_0/2)\,(K/K_t)$$

the result would be 388 916 cycles per sec. instead of the experimental value given above, namely 388 930 cycles per sec.

An analysis similar to the above was also made for the response occurring at a frequency of approximately 385 kilocycles per sec., with a view to explaining why the quartz disc oscillated more readily at 389 than at 385 kilocycles per sec. The results of the two measurements are given in Table 2. The two values of S were obtained at a few minutes' interval, and are therefore

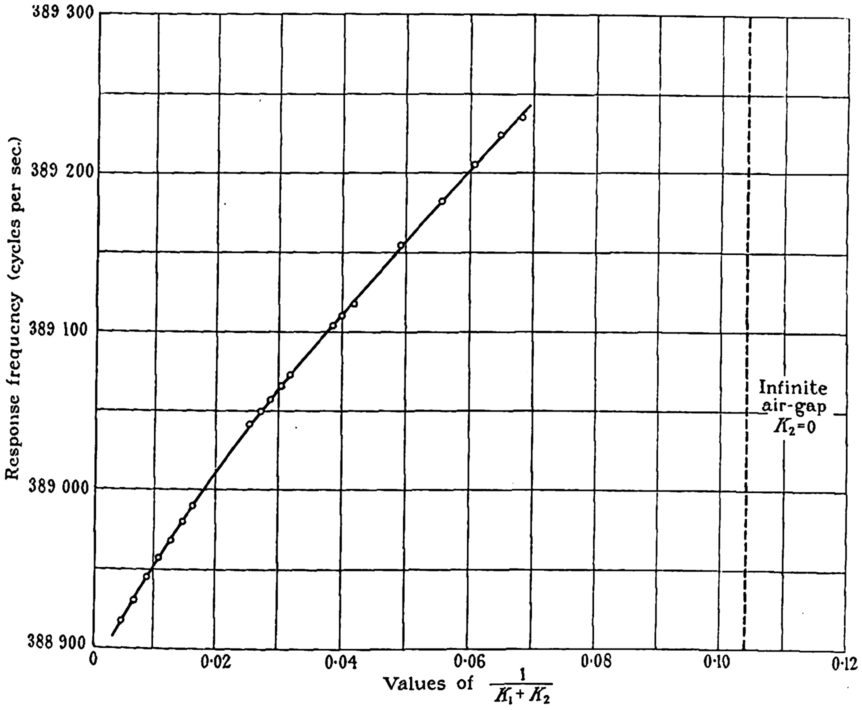

FIG. 13.—Relation between response frequency of the resonator and air-gap.

comparable. They would not be comparable if they had been obtained under different atmospheric conditions.

The reason why the quartz disc oscillates more readily at the higher frequency is now obvious from Table 2.

TABLE 2.

	First response	Second response
K_1 ($\mu\mu$F)	9·6	9·4
K ($\mu\mu$F)	0·018	$0{\cdot}013_3$
S (ohms)	400	540
f_0 (cycles per sec.) ..	388 890	385 210
Logarithmic decrement ..	55×10^{-6}	55×10^{-6}

The logarithmic decrement is approximately the same in both cases, but its constituent parts are different. In one case S is small and K is large; this is equivalent to saying that the damping is small and that a relatively large proportion of the quartz takes part in the vibration. For the second response, S is rather larger, and K is smaller. The damping is therefore larger, and the vibrations take place over a smaller portion of the face of the disc. Alternatively, a small K might indicate that the vibrations in certain parts of the disc are opposite in phase to the vibrations in other parts.

VALVES.

For most of the tests a D.E.R. valve was used. The values of g and m, which occur in the equation $i = g(v + me)$, were determined from the characteristics. They are given in Table 3.

TABLE 3.

D.E.R. Valve No. 3343.

Plate current	Plate conductance g
mA	mho × 10^{-6}
0·5	27
1·0	31
2·0	40
3·0	41·7

Amplification factor $m = 8{\cdot}6$

The tests on the quartz oscillator were made with 100 volts between the plate and the filament, and 2 volts on the filament. Under those conditions the plate current was 3 mA when the grid was kept at filament potential by means of a grid leak or in any other way.

In some cases a D.E.P. 610 valve was used for comparison with the D.E.R. valve. The filament voltage was 6·4 and the plate voltage 100. The amplification factor m was approximately 8, and the conductance g was as given in Table 4. With the grid at filament potential, the plate current was 15mA for a plate voltage of 100.

Inter-electrode Conductances and Capacities of the D.E.R. Valve.—The inter-electrode capacities and conductances of the valve are represented diagrammatically by Fig. 14. The three pairs of quantities were measured on the Schering radio-frequency bridge by a method analogous to that described two years ago by Hartshorn.* There were slight modifications because the radio-frequency bridge and the bridge used by Hartshorn are not identical. The results obtained are given in Table 5. The measurements were taken with the filament hot, and do not differ much from the results obtained with the filament cold.

TABLE 4.

Valve D.E.P. 610.

Plate current	Plate conductance g
mA	mho × 10^{-6}
5	290
10	260
15	200

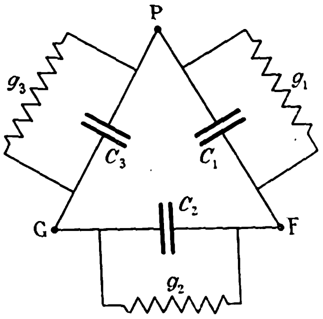

FIG. 14.

TABLE 5.

D.E.R. Valve.

$\mu\mu$F	mho × 10^{-6}
$C_1 = 4{\cdot}0$	$g_1 = 0{\cdot}2$
$C_2 = 6{\cdot}4$	$g_2 = 0{\cdot}5$
$C_3 = 2{\cdot}4$	$g_3 = 0{\cdot}05$

The relatively large capacity between grid and filament is due to the extra terminals between which the grid leak is inserted. The capacities are accurate to within 0·2 $\mu\mu$F, but the accuracy of the conductance figures is much less; it is probably 30 per cent, and might be as low as 50 per cent. To obtain accurate values, the valve should have been screened.

GRID RESISTANCES.

The grid resistances used were Loewe high-vacuum resistances, type FZ 128, which are platinized glass rods enclosed *in vacuo*.

The resistances were measured on a Wheatstone bridge and also on the Schering radio-frequency bridge, at a frequency of approximately 400 000 cycles per sec.

---

* See Reference (7).

The results are given in Table 6.

For the radio-frequency measurements it was assumed that the grid resistances were equivalent to a pure resistance in parallel with a pure capacity. In the radio-frequency measurements the amplitude of the alternating voltage applied to the resistances was 4 volts; measurements were also taken with an amplitude of 10 volts on the 1-megohm grid leak, and no difference could be detected.

TABLE 6.

Loewe Grid Resistances.

Nominal resistance	Conductance		Parallel capacity at 400 000 cycles per sec.
	To direct current	At 400 000 cycles per sec.	
megohms	mho × 10^{-6}	mho × 10^{-6}	μμF
3	0·34	0·36	0·1
2	0·43	0·45	0·2
1	0·87	0·8	0·1
0·5	1·78	1·7	0·1
0·25	4·4	4·5	0·2
0·1	11·1	11·2	0·2
0·075	11·9	12	0·2
0·05	17·0	17	0·3

The accuracy of the radio-frequency measurements is well within 5 per cent.

OSCILLATORY CIRCUITS.

The circuit used during the greater part of the investigation had an inductance of 160 μH, a self-capacity of 20 μμF and a total resistance of 2·08 ohms. In series with the condenser was a vacuo-junction of resistance 1·12 ohms, so that the resistance of the coil, leads and condenser was approximately 0·96 ohm.

In some of the experiments another circuit was used. Its inductance was 325 μH and its self-capacity 25 μμF. The total resistance was 4·3 ohms, 1·1 ohms being due to the vacuo-junction and 3·2 ohms to the coil, leads and condenser. The inductances were measured in each case by the capacity-variation method at frequencies in the neighbourhood of 400 000 cycles per sec., and the accuracy is probably better than 0·5 per cent.

With the D.E.P. 610 valve the currents in the condenser were large, and a thermo-junction with constantan heater was used instead of the vacuo-junction. The heater resistance was 0·61 ohm both on direct current and at a frequency of 390 000 cycles per sec. The total resistances of the two circuits were then 1·57 ohms and 3·8 ohms respectively.

Throughout the paper the term "total capacity in the oscillatory circuit" includes the self-capacity of the circuit and the parallel inter-electrode capacity C_1 between the plate and the filament.

Complete Circuits.—The circuits used are shown in Figs. 15 and 16. The telephones had a total resistance of 300 ohms to direct current, and a by-pass condenser of 0·02 μF was connected between the filament and the screen of the condenser of the oscillatory circuit. Resistance could be added at B in the oscillatory circuit.

Measurement of Alternating Voltage across the Condenser.—The heater of the thermo-junction was in series with the condenser, and not in series with the coil, because the plate current also flows through the coil and would vitiate the readings. The R.M.S. voltage across the coil is then given by the well-known formula $V = I/(C\omega)$; the current I is itself obtained from the reading of the galvanometer. Each thermo-junction was calibrated at the outset of the investigation, and the heater current was found to be proportional to the galvanometer deflection, as read on a square-law scale. The galvanometer is a moving-coil instrument and the scale is at a distance of 150 cm from the mirror.

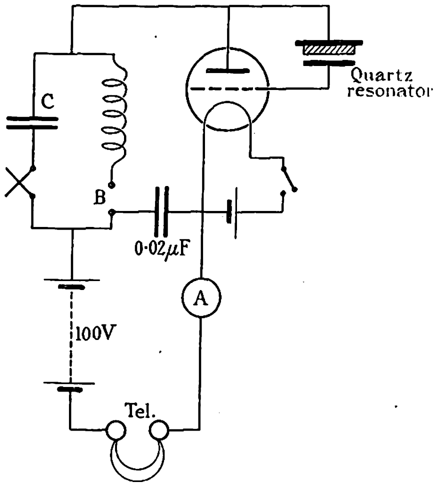

FIG. 15.—Plate-to-grid connection.

The instrument repeats with an accuracy of about 0·2 per cent, but the absolute value of the voltage across the condenser is only known to the accuracy of the standard milliammeter used in the calibration of the thermo-junctions. This was about 0·5 per cent. It is clear that a high degree of accuracy in the absolute value is not necessary in the present case.

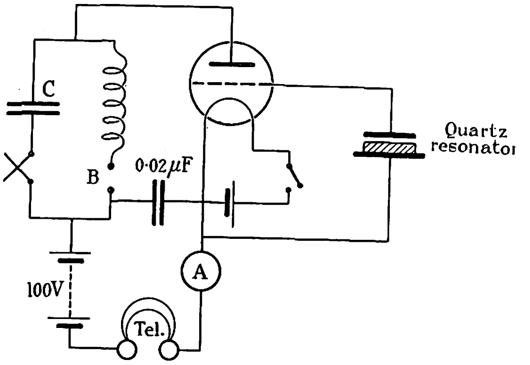

FIG. 16.—Filament-to-grid connection.

Measurement of Frequency.—The inductance coil of the quartz oscillator was very loosely coupled to the grid coil of a sensitive tuned-anode amplifier. The output coil of an auxiliary valve-oscillator was also made to induce in the amplifier coil, but was given by trial a position such that its coupling to the inductance coil of the quartz oscillator was as small as possible. The auxiliary generator was provided with variable condensers which ensured smooth and continuous variation of frequency. One of the condensers gave a variation of 2·65 cycles per sec. for 1 $\mu\mu$F, and it was a simple matter to read to within 0·1 $\mu\mu$F.

The oscillations from the quartz oscillator and the oscillations of approximately the same frequency from the auxiliary generator are received and amplified by the first two stages of the tuned-anode amplifier; if the two radio frequencies are nearly equal, an audible beat tone is produced which is amplified in the last two stages of the amplifier and reproduced by the loudspeaker.

In order to compare the two radio frequencies, the condenser of the auxiliary generator is varied until the frequency of the beat tone coincides with the frequency of a tuning-fork. In the present case a tuning-fork of 1 000 cycles per sec. was used.

When the frequency of the quartz oscillator is varied by an alteration in one or more of the constants of its circuit the frequency of the beat tone alters, and the reading of the condenser of the auxiliary generator must be altered to restore coincidence between the beat-tone frequency and the tuning-fork frequency. Variations in the frequency of the quartz oscillator can thus be estimated from the readings of the condenser of the auxiliary generator.

This condenser is calibrated by taking readings corresponding to beat tones of various frequencies, the frequencies being those of known tuning-forks.

The absolute frequency is given by the multi-vibrator wavemeter. This instrument induces known frequencies, multiples of 20 000, in the tuned-anode amplifier. Any one of those frequencies can be reinforced at will by tuning the grid circuit of the amplifier. The condenser of the auxiliary generator is adjusted until its frequency coincides with the multi-vibrator frequency. Equality is indicated by a characteristic beat. Other characteristic beats indicate equality between the auxiliary generator frequency and multiples of 1 000, and also multiples of still smaller numbers. In the present case it was quite easy to obtain calibration points 500 cycles per sec. apart.

The variations in frequency due to variations in the

FIG. 17.—Relation between the frequency and capacity of the oscillatory circuit for various grid leaks.

Valve: D.E.R. H.T. voltage = 100; L.T. voltage = 2; R = 2·1 ohms; L = 160 μH; air-gap = 0·012 cm.

temperature of the quartz are much larger than many of the variations that we are concerned with here. It was found, moreover, that the temperature of the quartz was a function of the amplitude of its vibrations. Such effects were allowed for by returning to a standard state between successive readings. In parallel with the calibrated condenser A of the auxiliary generator was a small condenser B by which any frequency drift could be corrected. The following example will illustrate the mode of procedure: Suppose it is desired to obtain a relation between the frequency of the quartz oscillator and the reading C of the condenser in the oscillatory circuit. Condenser C is set at a standard value C and condenser A at a standard value A. The other condensers of the auxiliary generator are varied until the beat tone is, say, 1 000 cycles per sec. Condenser C is moved to a value C_1 and A is altered until the beat tone is again 1 000, to A_1, say, giving the frequency difference looked for. Condensers A and C are then brought back to A and C, and the beat tone should then be 1 000. If there has been a small drift, it is taken on B, and the whole process is repeated for other values C_2, C_3, etc., of the condenser C. Variations of the quartz circuit are measured in the same way, and the complete set of results afterwards correlated. Only a single measurement of the absolute frequency is therefore necessary. In practice several were taken to serve as checks.

Relation between Frequency and Total Capacity in the Oscillatory Circuit.—A set of curves, reproduced in Fig. 17, was obtained by the method described in the previous Section. Simultaneous readings of the condenser of the auxiliary generator, of the deflection of the galvanometer spot and of the milliammeter in the plate circuit, were taken, and, for correcting drifts, readings were frequently taken for one and the same setting of the condenser in the quartz circuit. Curves were obtained with grid leaks of widely different values; the actual figures are given in the table in Fig. 17.

The capacity in Fig. 17 is the total capacity C, obtained by adding to the condenser reading 20 $\mu\mu$F for the self-capacity of the oscillatory circuit, 4 $\mu\mu$F for the inter-electrode plate-to-filament capacity C_1 and 6 $\mu\mu$F for the stray capacity between the plate lead and the leads of the by-pass condenser.

The shape of the curves confirm in a general way the conclusions arrived at by theoretical considerations on pages 270 and 275; namely, that

(i) With the resonator connected between the plate and the grid:

- (*a*) The frequency increases when C decreases;
- (*b*) The rate of variation increases as C decreases;
- (*c*) The greater the conductance of the grid leak, the higher the frequency; and
- (*d*) The rate of variation of frequency for a given value of C is greater with large grid conductances than it is with small grid conductances.

(ii) When the resonator is connected between the grid and the filament:

- (*a*) The frequency decreases when C increases;
- (*b*) The rate of variation of frequency increases as C increases;
- (*c*) The greater the conductance of the grid leak, the lower the frequency; and
- (*d*) The rate of variation of frequency for a given value of C is greater with large grid conductances than it is with small grid conductances.

The curves obtained when there was no added grid resistance do not fit in well with the others. The reason is that when no grid leak was used, simultaneous oscillations were produced at two different frequencies, as described on page 276, even with the plate-to-grid type of connection. It is quite conceivable that the mode of vibration under investigation, giving the frequency of approximately 389 kilocycles per sec., would be affected by the other, of frequency approximately 385 kilocycles per sec.

When the resonator is connected between the grid and the plate, the frequency without a grid leak should be slightly lower than the frequency with a grid leak. In the present case, however, it was found to be 0·9 cycle per sec. higher than with a grid leak of 3 megohms.

Another reason why it is better to consider only those curves obtained with grid leaks is that the added grid conductance, even though small, fixes the grid potential. With the D.E.R. valve used, the plate current was only 2·7 mA when there was no grid leak and when no oscillations were being maintained; with a grid leak, the corresponding value was 3·0 mA.

The next step is to calculate the frequency at various condenser readings and to compare the results with the curves of Fig. 17. This has been done for both types of connection for the case when the added grid conductance was $0{\cdot}36 \times 10^{-6}$ mho.

Consider first the plate-to-grid type of connection. The general procedure is to select particular values of α between the limits $\alpha = 1$ and $\alpha = 1{\cdot}301$, and to calculate β from equation (35) and then C from equation (45). The frequency is given by $f = f_0(\frac{1}{2} + \frac{1}{2}\beta)$.

The computation is, however, greatly simplified by making use of the fact that, as α varies between its limits 1 and 1·3, as given by equation (46), β only varies between the values $1 + (6 \times 10^{-4})$ and $1 + (7 \times 10^{-4})$. Regarding first β as constant and equal to the latter value, the frequency is calculated from equation (44) or (47).

The circuit variables were as follows:—

$C_2 = 6{\cdot}4\ \mu\mu\text{F}$
$C_3 = 2{\cdot}4\ \mu\mu\text{F}$
$K_3 = 15\ \mu\mu\text{F}$
$C_5 = 24\ \mu\mu\text{F}$
$\omega_0 = 2{\cdot}442 \times 10^6$ per sec.
$R = 2{\cdot}1$ ohms
$L = 160\ \mu\text{H}$

The value of C_0 is also required; it is calculated from L and ω_0 and found to be 1 047 $\mu\mu$F, It would be found that, with this value of C_0 and the values of C as read on the curves of Fig. 17, the calculated frequency curves would be 4 $\mu\mu$F to the right of the experimental curves. It is therefore necessary to alter C_0 slightly, so as to obtain agreement. An approximate formula for C_0 in terms of the experimental points of cut-off, C' and C'', is

$$(C_0/\beta) = \tfrac{1}{2}(C' + C'') + \tfrac{1}{2}C_3$$

The experimental cut-offs of the two curves under consideration are 1 043 and 1 040 $\mu\mu$F, and C_0, as calculated from the approximate formula, is 1 043 $\mu\mu$F. We shall, for convenience, adopt this value throughout the paper.

There is not much to choose between the two determinations of C_0. In the first case, the inductance L of the oscillatory circuit is required; it is not known, however, to much better than 5 parts in 1 000. In the second case, the final experimental figures for C' and C'' demand the estimation of the stray capacity between the leads connecting the plate and the filament to the condenser terminals. This stray capacity was taken as 6 $\mu\mu$F, which is perhaps under-estimated. Perfect agreement would be obtained by making it 10 $\mu\mu$F. The alternative, which has been adopted here for convenience, is to suppose L slightly larger, namely, 160·6 μH; and C_0 correspondingly smaller, namely, 1 043 $\mu\mu$F instead of 1 047 $\mu\mu$F.

TABLE 7.

Resonator Connected between Plate and Grid.

C	$a-1$	$f=389\,000+$	f (adjusted to fit the experimental value for large values of C) $= 389\,000 +$
1	2	3	4
1 250	0·008	9·4	16·4
1 150	0·015	10	17
1 100	0·027	10·6	17·6
1 070	0·053	12·5	19·5
1 050	0·142	18	25
1 047	0·189	21	28
1 045	0·243	24	31
1 044	0·283	27	34

Calculations have been performed using the values already adopted for the various constants, and the results are given in Table 7. Col. 3 gives the calculated frequency. This frequency is, for large values of the capacity, say 1 150 $\mu\mu$F, approximately 7 cycles per sec. below the experimental value. This constitutes an error of about 6 per cent in the value of $f - f_0$. Greater accuracy cannot, however, be expected, since repeated experimental work has proved that, even in the simpler case of a quartz resonator, the formula

$$f = f_0\left\{1 + \tfrac{1}{2}(K/K_t)\right\}$$

does not account for the change of frequency which actually accompanies a change in air-gap.

The values in col. 4 of Table 7 were obtained by adding 7 to the figures in col. 3; this is equivalent to making the theoretical curve fit the experimental curve for large values of C, that is, for points where the rate of change of frequency with respect to C is small. A fair test of the theory is then to see how far the theoretical curve fits the experimental curve at the other points, in particular at points where the rate of variation of frequency is large. The two curves are shown in Fig. 18; the theoretical curve bends more sharply than the experimental curve. If the value of C_2 were made slightly larger than 6·4 $\mu\mu$F the two curves could be made to fit everywhere. In fact, the effective value of C_2 is larger than 6·4, because the grid leak introduces from 0·1 to 0·2 $\mu\mu$F, and there must be some capacity between the filament lead and the lead joining the resonator to the grid of the valve.

TABLE 8.

Resonator Connected between Grid and Filament.

C	$1-a$	$f = 389\,000 +$	f (adjusted to fit the experimental value for small C) $= 389\,000 +$
850	0·0014	8·8	12·1
950	0·0029	8·6	11·9
1 000	0·0065	8·4	11·7
1 020	0·013	8·0	11·3
1 030	0·025	7·1	10·4
1 035	0·049	5·5	8·8
1 038	0·113	1·0	4·3
1 039	0·200	− 5·5	− 2·2
1 039·5	0·325	− 15	− 12

Similar calculations were performed for the grid-to-filament type of connection, and the calculations are given in Table 8.

TABLE 9.

Resonator Connected between Grid and Filament.

C	$1-a$	$f = 389\,000 +$	f (adjusted to fit the experimental value for small C) $= 389\,000 +$
850	0·003	8·7	12·1
950	0·006	8·5	11·9
1 000	0·014	8	11·4
1 020	0·027	7	10·4
1 030	0·052	5·2	8·6
1 035	0·095	2·3	5·7
1 038	0·190	− 1·0	− 2·4
1 039	0·285	− 12	− 9

The value of C_3 was taken as 2·5 $\mu\mu$F as measured on the Schering bridge. The theoretical curve and the experimental curve are shown in Fig. 18. Here, again, the theoretical curve has a sharper bend than the experimental curve. The points marked on or near the experimental curve were calculated for a value of C_3

equal to $3 \cdot 7\ \mu\mu$F, and a value of C_0 equal to $1\,044 \cdot 6$; the values are given in Table 9.

It is thus seen that a larger value of C_3, accompanied by a slight adjustment of C_0, brings the theoretical and experimental values into almost complete agreement. The small adjustment in C_0 is necessary to make the capacity C, at which the oscillations cease, equal in both cases. The alteration of C_3 is in the right direction because, in addition to the capacity between grid and plate, measured on the bridge, there is some capacity between the lead connecting the plate to the condenser, and the lead connecting the grid to the resonator. This may well have been $1\ \mu\mu$F.

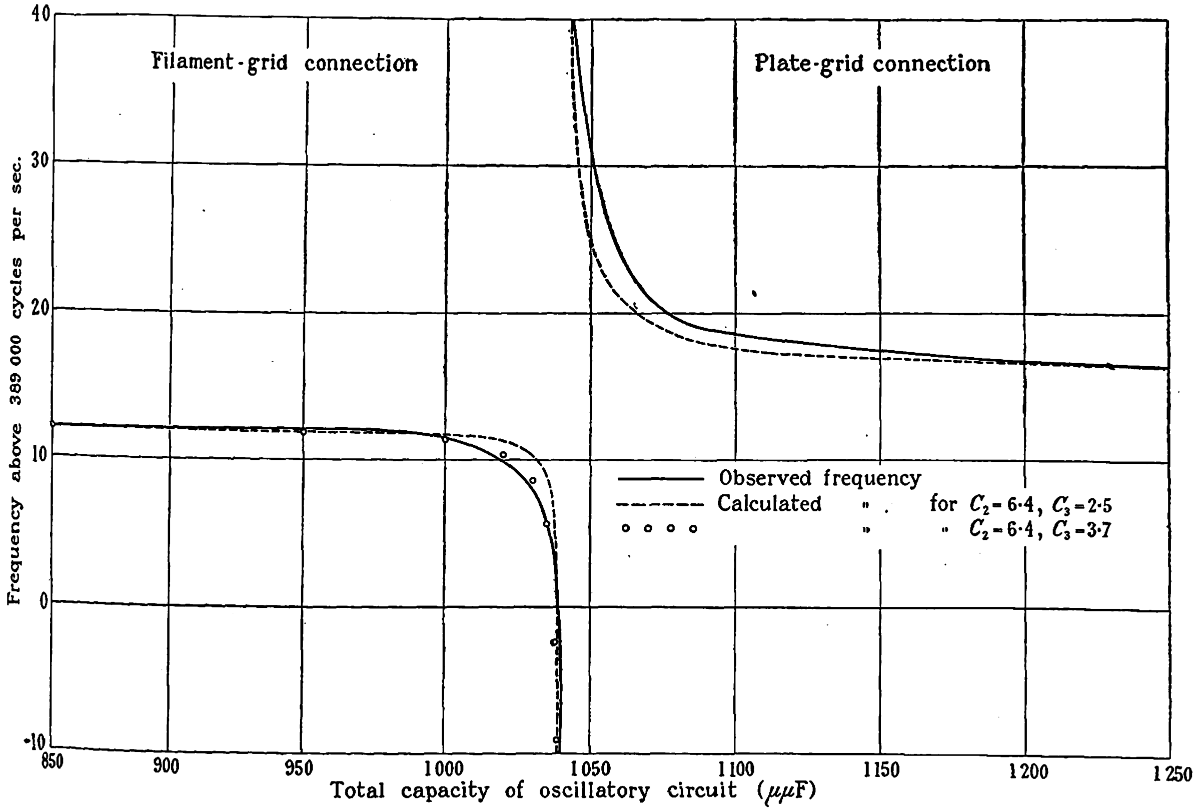

FIG. 18.—Comparison between calculated and observed frequencies for various capacities.

Valve: D.E.R. $L = 160\ \mu$H; $R = 2 \cdot 1$ ohms; grid leak $= 0 \cdot 36 \times 10^{-6}$ mho.

The frequency for large values of C in the plate-to-grid type of connection, and the frequency for small values of C in the grid-to-filament type of connection, should be almost equal to each other, and should be independent of the grid leaks. The asymptotic frequency is given by equation (49). Fig. 17 shows, however, that the asymptotic value varies by one or two cycles when the grid conductance is increased from $0 \cdot 4 \times 10^{-6}$ mho to 10 or 12×10^{-6} mho. This variation may be accounted for by the small capacity introduced by the grid leaks.

When it is desired to change from one type of connection to the other, the resonator lead is disconnected, say, from the plate, and connected to the filament; the other resonator lead is left permanently connected to the grid. In this process of changing over, the capacity between the two resonator leads may be altered by a considerable amount, say $1\ \mu\mu$F. This alters the value of K_3 and therefore of C_5. Suppose in one case C_5 was $24\ \mu\mu$F and in the other case $23\ \mu\mu$F. The corresponding difference in frequency, obtained from equation (49), is just 3 cycles per sec., which is about equal to the difference found experimentally.

Curves I and II, Fig. 17, exhibit a decrease of $|df/dC|$ with decreasing values of C in the neighbourhood of the cut-off point. This decrease is not in accordance with the approximate formulæ worked out in the paper; it is nevertheless a real effect, and not an experimental error. The reason why it is apparent with large grid conductances and not with small ones may be due to the fact that the range of capacity over which this effect occurs becomes smaller and smaller as the grid conductance is decreased.

This divergence between predicted results and experimental results might be due to the variation of the valve plate conductance g with plate current. The decrease in conductance g would tend to reduce the increase in α, as can be seen from equation (37). It is quite as possible, however, that the cause lies in the approximations made when establishing the formulæ.

Relation between Frequency and Inter-electrode Capacities.—It has been shown on pages 000 and 000 that the frequency decreased with C_2 and that the modulus $|dn/dC_2|$ of the rate of change also decreased with C_2

for both types of connection. It has also been shown that the frequency decreases with C_3 for both types of connection.

In order to confirm this prediction, a small-variable condenser, of capacity 4 to 24 $\mu\mu$F, was placed in parallel with either C_2 or C_3, and the frequency was measured for various settings of that condenser.

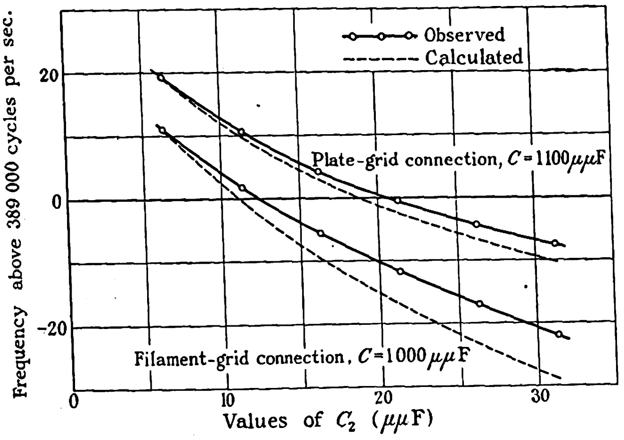

FIG. 19.—Relation between frequency and filament-grid capacity C_2.

Valve: D.E.R. $L = 160\ \mu$H; $R = 2{\cdot}1$ ohms; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho; $C_3 = 2{\cdot}4\ \mu\mu$F.

The experimental curves are shown in Figs. 19 and 20, and their shape confirms the theoretical conclusions. The theoretical curves were made to fit the experimental curves at one point only, namely, the point for which $C_2 = 6{\cdot}4$ and $C_3 = 2{\cdot}4$.

The theory is thus being tested for frequency differences from a point on the curve, not for frequencies above f_0. The reason for this has already been given on page 271.

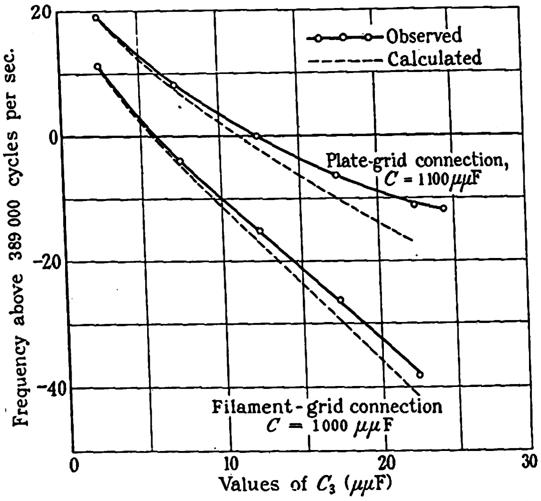

FIG. 20.—Relation between frequency and plate-grid capacity C_3.

Valve: D.E.R. $L = 160\ \mu$H; $R = 2{\cdot}1$ ohms; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho; $C_2 = 6{\cdot}4\ \mu\mu$F.

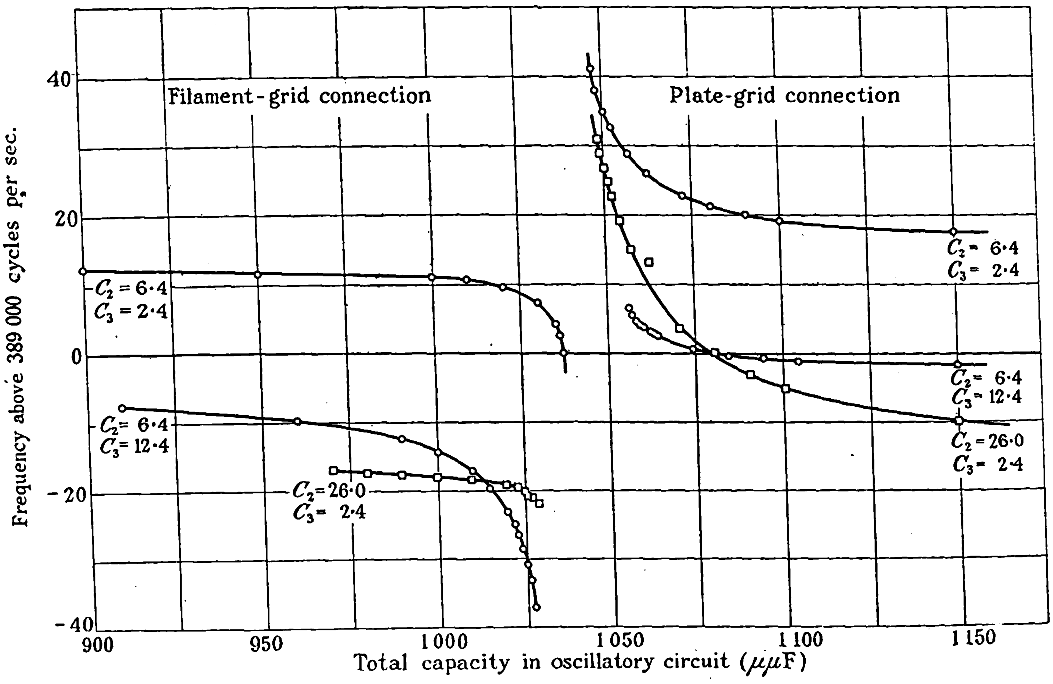

FIG. 21.—Relation between frequency and inter-electrode capacities.

Valve: D.E.R. $L = 160\ \mu$H; $R = 2{\cdot}1$ ohms; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

Equations (47) and (70) were used to calculate Δf, so that the effect of the resistance R and the inter-electrode conductances on the frequency differences were neglected. The values taken for C_2, C_3 and K_3 were obtained by separate measurements, entirely independent of the experiments on the oscillator. The theoretica curves could be made to fit the experimental curves much more nearly by slightly altering those values, but it has not been deemed necessary to do this here.

Fig. 21 shows the frequency variations with respect to C for various values of C_2 and C_3. The shape of the curves agrees with the deductions made on theoretical grounds.

As an example, consider the plate-to-grid type of connection, for which df/dC is given by equation (48). It is always negative and increases numerically with C_2. Hence, for given values of C_3 and K_3, the slope of the curve is greater when C_2 is large than it is when C_2 is small. This point is well borne out by the experimental curves.

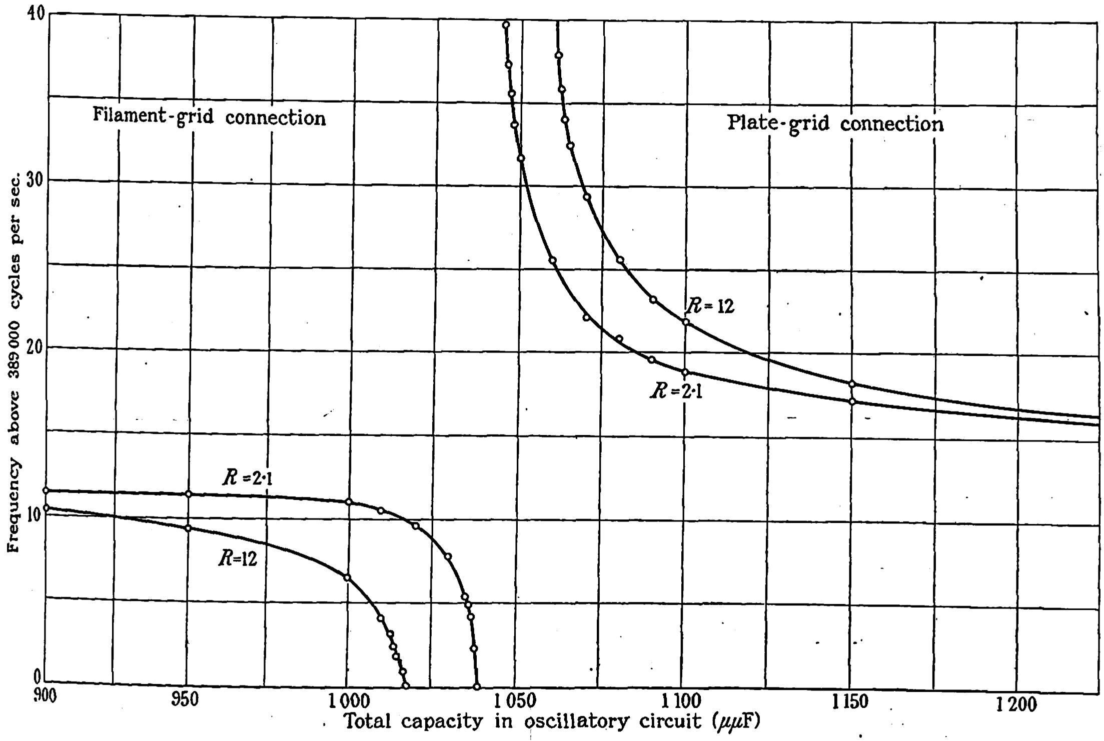

FIG. 22.—Relation between frequency and resistance of oscillatory circuit.
Valve: D.E.R. $L = 160\ \mu$H; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

Relation between Frequency and Resistance of the Oscillatory Circuit.—Curves of frequency against total capacity C were taken for various values of the resistance R of the oscillatory circuit. In order to alter the resistance of that circuit, the link closing the circuit was replaced by non-inductive resistances. The resistances were originally made for the measurement of the effective resistance of circuits at radio frequencies by the resistance-variation method, and their effect on the inductance and on the capacity of the circuit is known to be negligible.

The curves obtained are shown in Fig. 22. The variations are in the direction predicted on page 271, and when the oscillatory circuit is considerably out of tune the frequency is practically independent of the resistance. The actual variations in frequency are, however, larger than the figures to be expected from equations (37) and (68). These formulæ give α in terms of R, other things being the same, and the frequency is calculated by the formula

$$f = f_0 + \frac{1}{2} f_0 \frac{K}{K_t} \frac{\alpha K_2 + C_5}{\alpha (K_1 K_2 / K_t) + C_5}.$$

For any given value of the total capacity C, the amplitude of oscillations decreases considerably with R; it is to be expected that the effective anode conductance g alters considerably in the process. Even then the formula could not account for the large variations of frequency taking place.

As an example, with $g_2 = 0{\cdot}5 \times 10^{-6}$, $g_3 = 0{\cdot}05 \times 10^{-6}$, $g_4 = 0{\cdot}8 \times 10^{-6}$, and $g = 25 \times 10^{-6}$, when R increases from 2 to 12 ohms, the frequency for $C = 1\,100\ \mu\mu$F increases by 0·7 cycle per sec., according to the formula. If at the same time g is supposed to have increased from 25×10^{-6} to 40×10^{-6}, the total calculated increase in frequency is 1 cycle per sec.

The experimental figure is 3 cycles per sec. Part of the difference may, of course, be due to the uncertainty in the values of the inter-electrode conductances g_2 and g_3.

It must be remembered that equation (37) for α is only an approximation, which supposes that $HE - GF = 0$. This is equivalent to writing $\beta_2 = 0$ [see equations (29) and (36)]. But when a constant amplitude is being maintained, we have, from equation (19), $\beta_2 + SK = 0$. The same expression also shows that, near the cut-off point, the terms H, W and F become important, especially when R is large. The error in the approximation is then larger.

Relation between Amplitude of Oscillations and Capacity *of Oscillatory Circuit.*—A number of curves were obtained for various values of added grid-to-filament conductance, ranging between zero and 12×10^{-6} mho. These are all reproduced in Fig. 23.

The shape of the curves is analogous to that which was predicted from theoretical considerations. The amplitude is small when the oscillatory circuit is considerably out of tune. As the capacity C is varied towards C_0, the amplitude increases more and more rapidly and reaches a maximum at a value of C which is not very different from C_0. From this maximum it decreases very rapidly and then drops suddenly to zero. The value of C at cut-off is very close to the value of C for maximum amplitude.

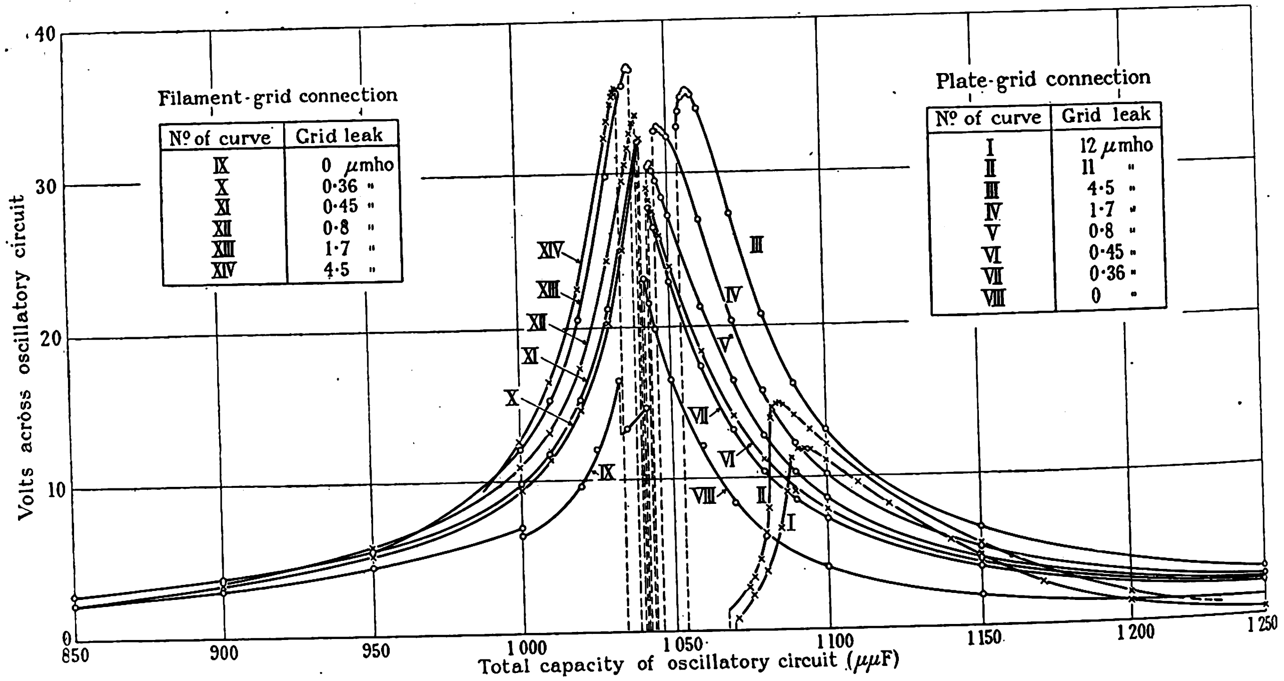

FIG. 23.—Relation between amplitude and capacity of oscillatory circuit.

Valve: D.E.R. $L = 160\ \mu$H; $R = 2 \cdot 1$ ohms.

It is seen from the curves that the largest maximum amplitude is given in one case by an added grid conductance of $4 \cdot 5 \times 10^{-6}$ mho, and in the other case by an added grid conductance of $1 \cdot 7 \times 10^{-6}$ mho. The formulæ developed do not explain this; on the contrary, the theoretical curves (Fig. 6) indicate that an increase in the grid conductance g_4 is accompanied by a decrease in maximum amplitude. It has already been mentioned, however, that other considerations arise; for example, the grid leak may tend to keep the mean potential of the grid at the most favourable place on the characteristic curve of the valve.

In Fig. 23 the amplitude curve for the filament-to-grid connection without any grid leak shows discontinuities at a few points. The reason for this is that the second mode of vibration already mentioned caused oscillations simultaneous with those under observation, for certain values of the capacity C.

On all other points there is fair agreement between theory and experiment. The plate-to-grid curves do not fall off as rapidly as the grid-to-filament curves, the reason being that C_2 was larger than C_3. The effect of the grid leaks on the cut-off point is in the direction predicted by theory, and the order of magnitude is also the same.

Oscillations could not be started in the filament-to-grid case when the added grid conductance was 11×10^{-6} mho or larger.

The maximum point and the cut-off point are nearer together in practice than was to be expected from the theoretical curves of Fig. 6, especially in the case when the added grid conductance was small, namely $0 \cdot 8 \times 10^{-6}$ mho. In fact, the points were so near together in practice that it was impossible to distinguish them. The reason for this divergence seems to be that the value of 400 ohms taken for S is too large. It was obtained by measurements on the quartz when used as a resonator. It is conceivable that, in an oscillator, the piece of quartz will vibrate itself more readily into the position giving minimum damping.

TABLE 10.

Type of connection	Added grid conductance	Range	
		Calculated	Observed
	mho × 10⁻⁶		
Plate-grid ..	0·8	1 540 to 1 053	1 800 to 1 044
Plate-grid ..	4·5	1 290 to 1 061	1 350 to 1 053
Filament-grid	0·8	850 to 1 036	800 to 1 040
Filament-grid	4·5	940 to 1 034	880 to 1 034

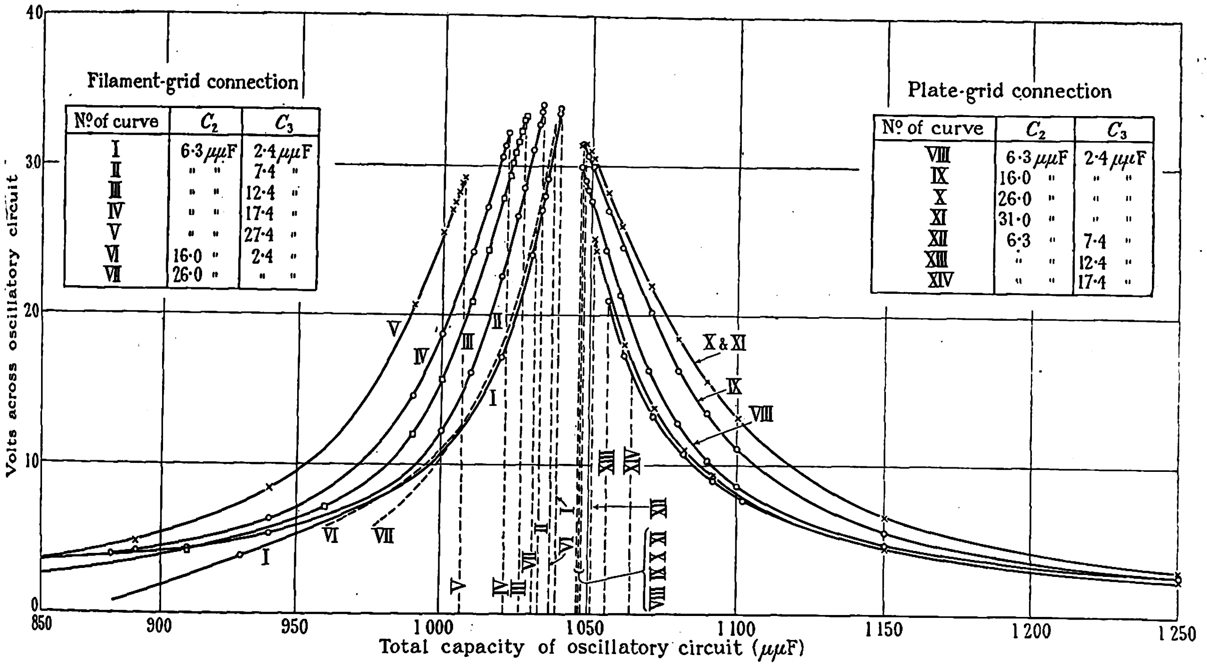

FIG. 24.—Relation between amplitude and inter-electrode capacities.

Valve: D.E.R. $L = 160\ \mu$H; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

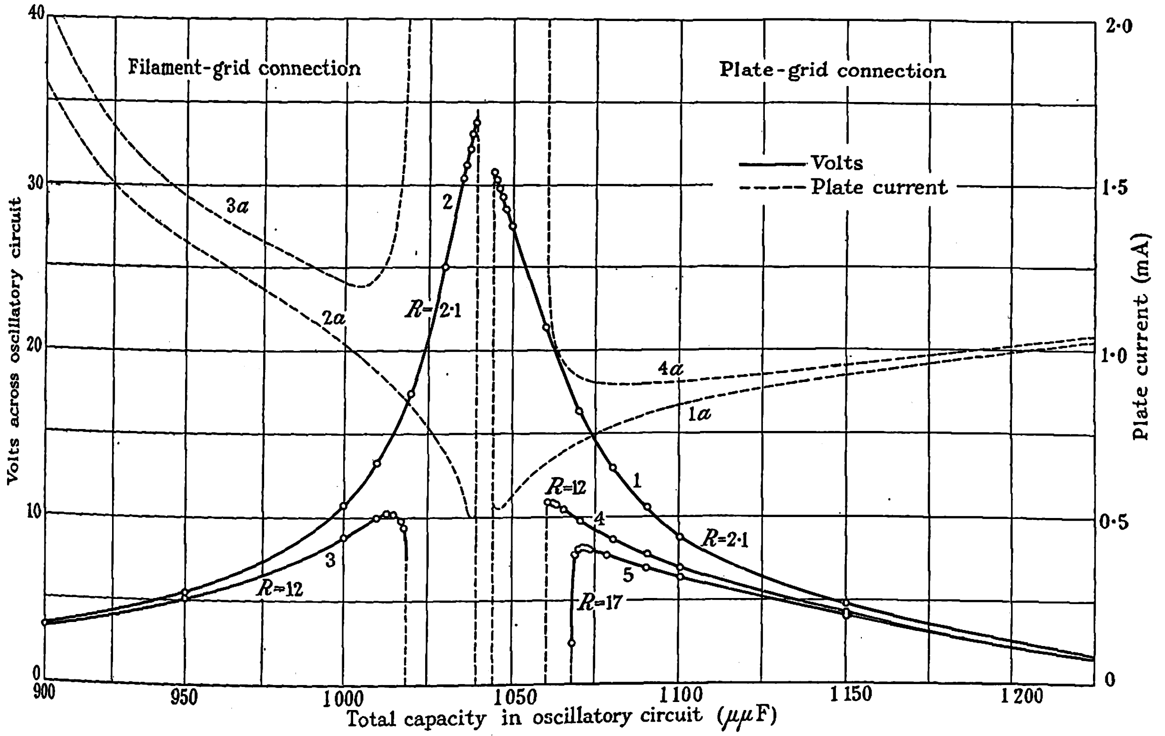

FIG. 25.—Relation between amplitude and resistance of oscillatory circuit.

Valve: D.E.R. $L = 160\ \mu$H; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

The difference between the range of capacity over which oscillations were maintained might also be accounted for by this over-estimation of S. In Table 10 some figures are given to show the difference.

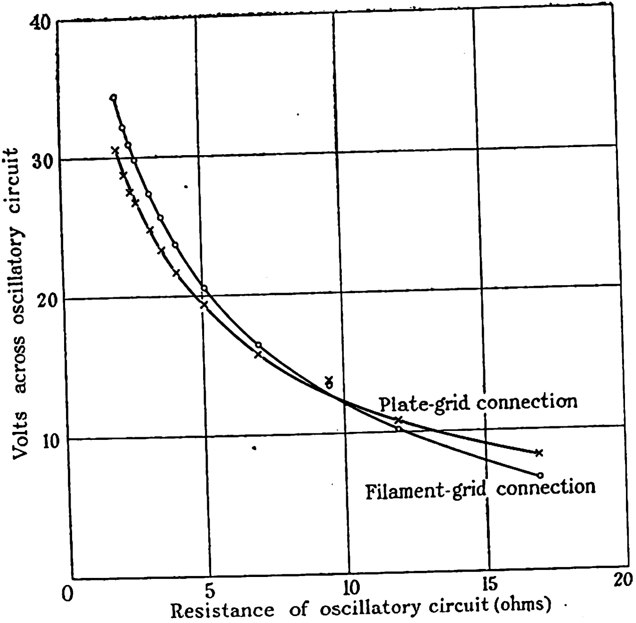

FIG. 26.—Relation between maximum amplitude and resistance of oscillatory circuit.
Valve: D.E.R. $L = 160\ \mu$H; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

Relation between Amplitude of Oscillations and Inter-electrode Capacities.—The experimental results are embodied in the curves of Fig. 24. The variations are in accordance with the theory.

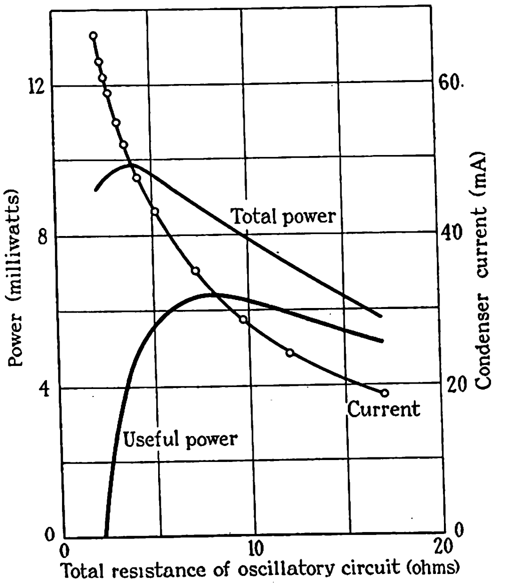

FIG. 27.—Relation between power dissipated and resistance of oscillatory circuit. Plate-grid connection.
Valve: D.E.R. $L = 160\ \mu$H; $R = 2{\cdot}1$ ohms; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

In the case of the plate-to-grid connection, the amplitude increases at first as C_2 is increased. There is an optimum value of C_2 past which the amplitude would decrease. In the present case this optimum seems to be between 26 and 31 $\mu\mu$F, since the curves for those two capacities are identical. No measurements were made with a capacity exceeding 31 $\mu\mu$F.

An increase in C_3, the capacity in parallel with the quartz resonator, is always disadvantageous, as shown by curves XII, XIII and XIV. Not only does the amplitude decrease, but the value of the capacity C at which the cut-off occurs is increased. This variation in the cut-off point is readily explained by the theory.

In the plate-to-grid connection, an increase in C_3 or K_3 is equivalent to a decrease in E in equation (54). The value of x required to satisfy the equation $\phi_2 = 0$ [see equation (55)] is therefore increased.

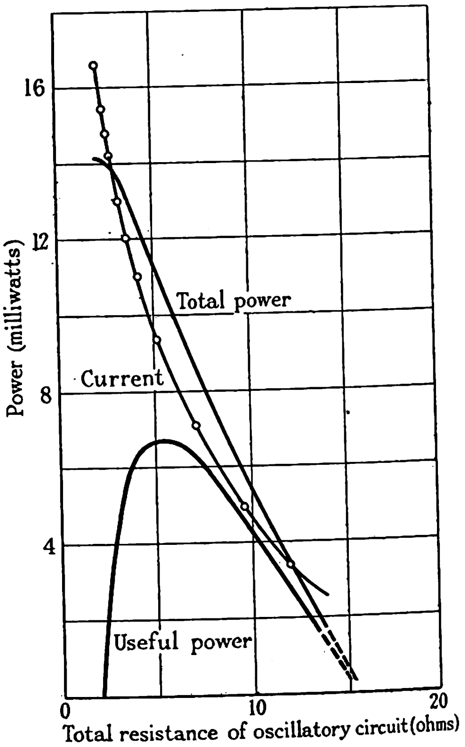

FIG. 28.—Relation between power dissipated and resistance of oscillatory circuit. Filament-grid connection.
Valve: D.E.R. $L = 160\ \mu$H; $R = 2{\cdot}1$ ohms; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

An increase in C_2, on the other hand, may or may not mean an increase in the coefficient E, depending upon whether C_2 is below or above its optimum value. Moreover, the coefficients in equation (54) may be such that $|\partial\phi_2/\partial C_2|$ is small over a large range of values of C_2. This seems to be the case here, and an alteration in C_2 has no appreciable effect on the cut-off.

Similar considerations show that in the filament-to-grid case an increase in C_2 or in K_3 always produces a decrease in the cut-off point. An increase in C_3 may or may not produce a decrease in the cut-off point. It does so in the present case. It is to be noted that a decrease in the cut-off capacity is not necessarily accompanied by a decrease in the maximum amplitude.

Relation between Amplitude of Oscillations and Resistance of the Oscillatory Circuit.—Complete amplitude curves for different resistances are shown in Fig. 25. When the resistance of the oscillatory circuit is large, the maximum amplitude is small, and the values of C for maximum amplitude and for cut-off are further apart than is the case with a low-resistance oscillatory circuit.

When the oscillatory circuit is considerably out of tune the amplitude is approximately inversely proportional to the impedance of the oscillatory circuit, which is nearly equal to

$$\omega_0 L/\sqrt{\{\omega_0^2 R^2 C^2 + (1 - \omega_0^2 LC)^2\}}$$

This expression is practically independent of R when $1 - \omega_0^2 LC$, that is, $1 - (C/C_0)$ is as large as, say, $0\cdot3$ or $0\cdot4$.

The added resistance, just as the added grid conductances, produces an earlier cut-off. This is in perfect agreement with the theoretical curves (Fig. 6). Theory and experiment both show, moreover, that the other limiting capacity, given by equations (42) and (73), is not appreciably altered by addition of resistance; the range is therefore approximately the same, whatever be the resistance of the oscillatory circuit, whereas it is greatly reduced by addition of grid conductance, or by an increase in the damping S of the quartz.

The curves in Fig. 26 give the maximum amplitude for various values of the resistance R of the oscillatory circuit. They confirm the prediction that the amplitude is approximately inversely proportional to the resistance of the oscillatory circuit. The departure from the hyperbolic law is also in the direction predicted. This rule is not confined to quartz oscillators: it is perfectly general, and demonstrates the importance of designing low-resistance coils for valve oscillators.

When the resistance of the oscillatory circuit is large, the maximum amplitude for the plate-to-grid connection is larger than the maximum amplitude for the filament-to-grid connection. This was found to be the case for all the valves and all the inductances used. From the theoretical curves (Fig. 6) one might have expected just the reverse phenomenon. Here, again, the mean grid

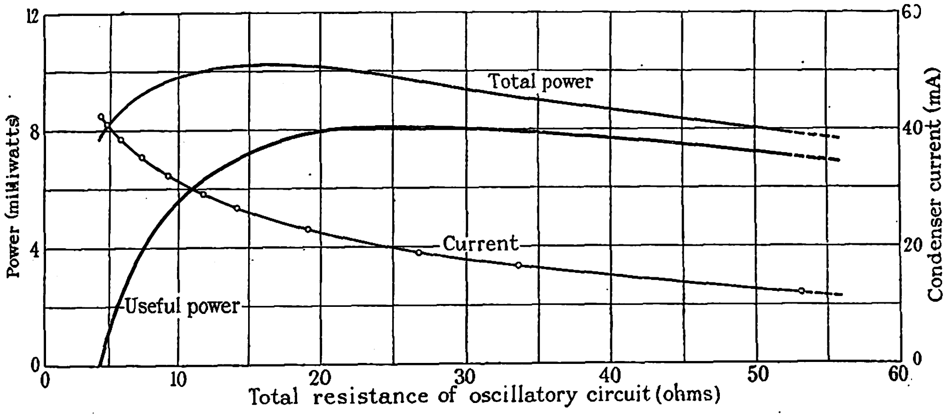

FIG. 29.—Relation between power dissipated and resistance of oscillatory circuit. Plate-grid connection.
Valve: D.E.R. $L = 325\ \mu$H; $R = 4\cdot3$ ohms; grid leak $= 0\cdot8 \times 10^{-6}$ mho.

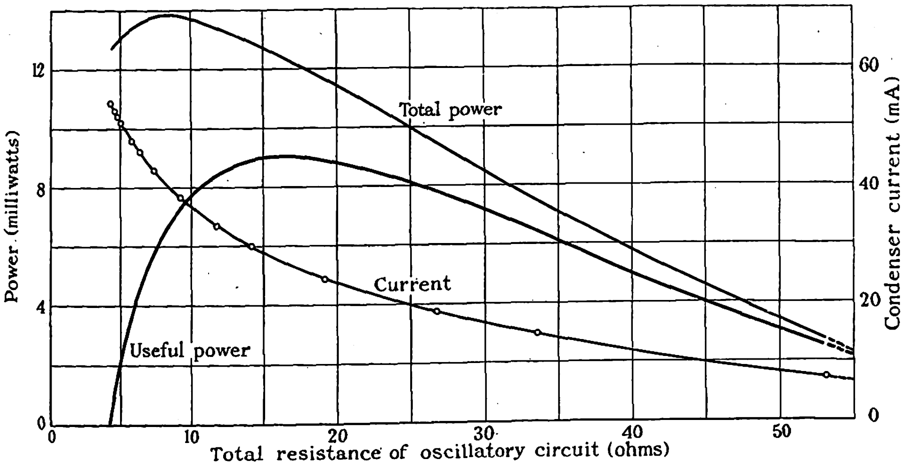

FIG. 30.—Relation between power dissipated and resistance of oscillatory circuit. Filament-grid connection.
Valve: D.E.R. $L = 325\ \mu$H; $R = 4\cdot3$ ohms; grid leak $= 0\cdot8 \times 10^{-6}$ mho.

potential is probably governed by other factors besides the grid leak and the amplitude.

The point could easily be studied further by eliminating x between the equations

$$\phi = 0 \quad \text{[see equation (54)]}$$

and

$$(\partial\phi/\partial x) = 0 \quad \text{[see equation (57)]}$$

solving for $1/g$ and assigning various values to R for both types of connections.

Relation between Power Dissipated and Resistance of Oscillatory Circuit.—In all the measurements described below, the condenser current measured was the maximum current with respect to the capacity C. It corresponds to the maximum ordinates of the curves of Fig. 25. It is not always possible or advisable to work at maximum amplitude, because the maximum amplitude is so very near to the cut-off position, especially when the resistance of the oscillatory circuit is low. In cases where a large power is taken from the oscillator, it is possible to work at maximum amplitude, because, as can be seen from curves III and V, Fig. 25, the maximum is flatter, and not too near to the cut-off position. Also, since curves III and V lie wholly within curves II and I, Fig. 25, on sudden removal of the load the oscillator will go on working at a stable point of curves II or I.

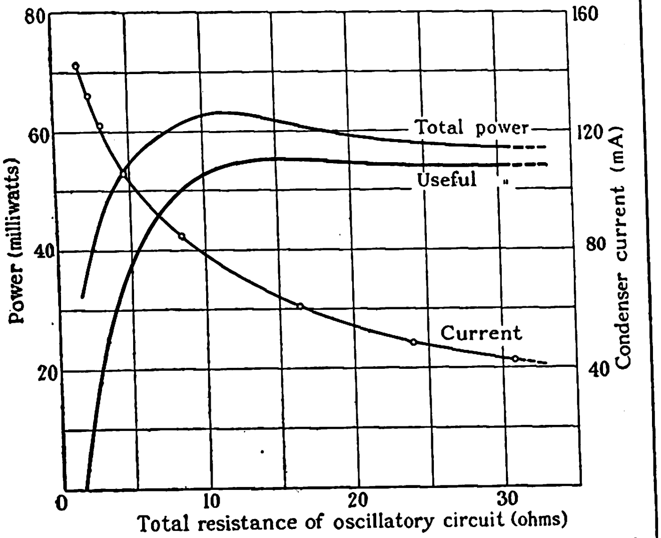

FIG. 31.—Relation between power dissipated and resistance of oscillatory circuit. Plate-grid connection.

Valve: D.E.P. 610. $L = 160\ \mu$H; $R = 1{\cdot}57$ ohms; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

For all the power measurements below, the added grid conductance was $0{\cdot}8 \times 10^{-6}$ mho.

For the sake of comparison, measurements were made with both types of connection, for the two circuits the constants of which are given on page 281 and the two valves the constants of which are given on page 280. The same plate voltage, viz. 100 volts, was used throughout.

The useful power is the product of the square of the current in the condenser C and of the added resistance R'. Under normal working conditions, R' is an equivalent series resistance, due to a coupled circuit or some other form of load. The total power is the product of $R + R'$ and the square of the condenser current. It is a more instructive figure than the former because it is dependent only on the sum of the resistances R and R', and not on R. It represents the available power in a circuit of zero inherent resistance.

If the amplitude were strictly inversely proportional to the resistance, the total power dissipated would vary in an exactly similar manner to the amplitude. A glance at Figs. 27 to 34 shows that this is not so. The total power would in practice be very small for a very small total resistance; as the total resistance is increased it reaches a maximum, and then decreases gradually. For large values of the total resistance, its variation becomes very similar to the variation of amplitude; for larger values still, no oscillations can be started.

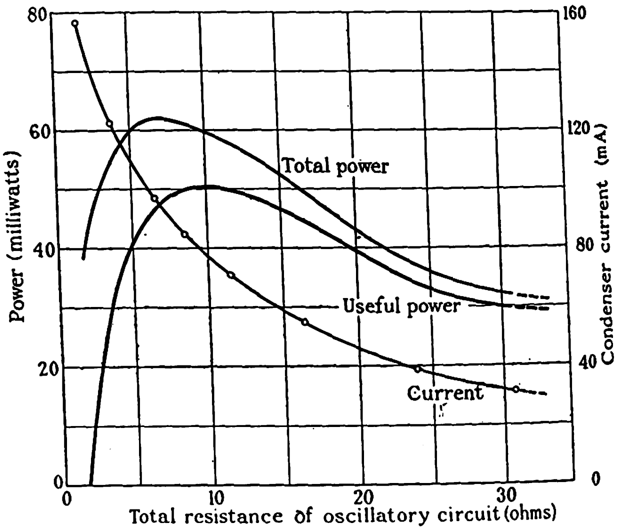

FIG. 32.—Relation between power dissipated and resistance of oscillatory circuit. Filament-grid connection.

Valve: D.E.P. 610. $L = 160\ \mu$H; $R = 1{\cdot}57$ ohms; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

The curves show in striking manner the difference between the plate-to-grid and filament-to-grid types of connection. In the filament-to-grid type, the maximum total power is in some cases higher than the corresponding power for the plate-to-grid connection. In all cases, however, the curve is sharper and the maximum power corresponds to a smaller total resistance than with the plate-to-grid connection. The plate-to-grid connection is therefore preferable, because it is advantageous to dispose of approximately maximum power over as wide a range of current as possible. Another advantage of the plate-to-grid connection is that subsidiary resonances of the quartz plate, in the neighbourhood of the main resonance frequency, do not produce secondary oscillations as readily as they seem to do with the filament-to-grid connection. On the other hand, for a given amplitude of plate voltage, the voltage across the quartz resonator is higher in the plate-to-grid type of connection than it is in the filament-to-grid connection. The swing E of grid voltage is, in general, smaller than half the amplitude V of the plate voltage. In consequence

$$|V - E| \geqslant |V| - |E| > |E|$$

The high-conductance valve gives, other things being equal, much more power than the low-conductance valve. Moreover, oscillations are maintained for a much larger range of the resistance $R + R'$ and the curve of total power dissipated against total resistance of the oscillatory circuit is much flatter with the high-conductance valve. This provides greater flexibility for the use of the maximum output, and is a distinct advantage.

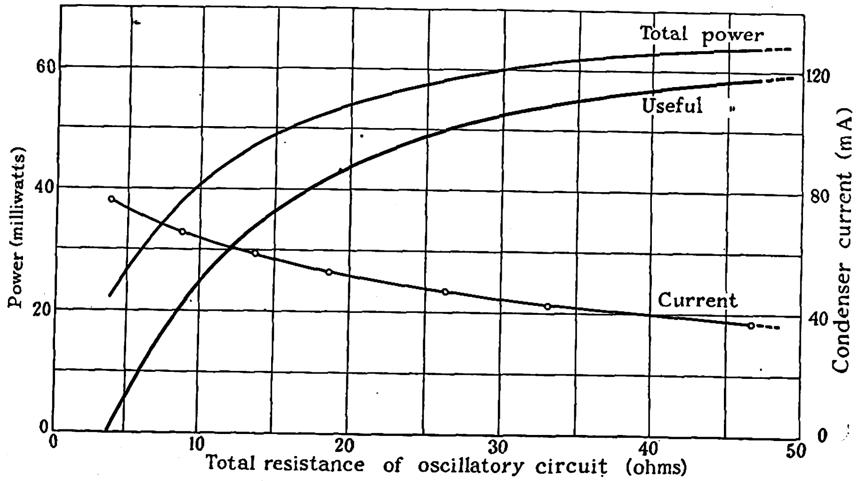

FIG. 33.—Relation between power dissipated and resistance of oscillatory circuit. Plate-grid connection.
Valve: D.E.P. 610. $L = 325\ \mu$H; $R = 3{\cdot}8$ ohms; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

The amplitude of the voltage across the condenser increases when the inductance L is made larger, and the capacity C correspondingly smaller. The increase in amplitude for a given resistance is not, however, in the proportion of the square of the inductance.

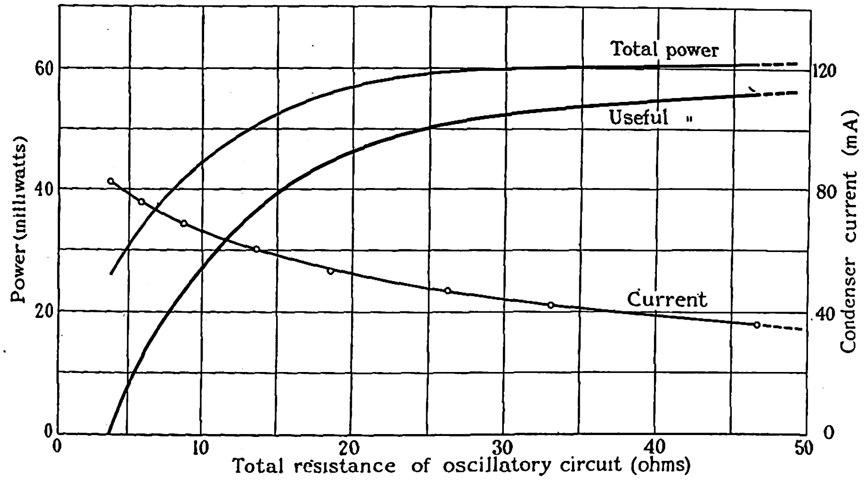

FIG. 34.—Relation between power dissipated and resistance of oscillatory circuit. Filament-grid connection.
Valve: D.E.P. 610. $L = 325\ \mu$H; $R = 3{\cdot}8$ ohms; grid leak $= 0{\cdot}8 \times 10^{-6}$ mho.

The maximum is not very different for the two inductances, but oscillations are maintained for a much larger range of total resistance, and the power curves are much flatter, with the high inductance. It is, therefore, advisable to work with a fairly large ratio of L to C_0. In the present case, with the D.E.R. valve, the ratio $L/C = 0{\cdot}6 \times 10^6$ is more advantageous for most purposes than the ratio $0{\cdot}15 \times 10^6$. The optimum ratio of L to C_0 depends upon the valve and the requirements of the user. Thus, with the D.E.P. valve the maximum power dissipated is approximately the same with the 160-μH and 325-μH coils. Suppose it is required to pass current through a resistance of 10 ohms and obtain as much power as possible. Figs. 31 to 34 show that the 160-μH coil is much more suitable than the 325-μH coil.

When the power is dissipated in a circuit of inductance L_1 and resistance R_1 coupled to the coil L the above considerations are not so important, because a new variable is provided by the mutual inductance M. The equivalent resistance $R + R'$ is equal to $R + \left\{(\omega^2 M^2 R_1)/(R_1^2 + \omega^2 L_1^2)\right\}$ and, with a given value of R_1, can be altered by altering M until the condition for maximum power is reached.

In the case of Figs. 27 and 28, oscillations could not be started with resistances of 24 ohms and above. In the other six cases oscillations could have been produced with resistances even larger than the largest used. In the case of Fig. 33, the maximum power was not reached although the total resistance was nearly 50 ohms.

The modifications of the Pierce circuits with a view to obtaining large powers from a crystal have not been included in this investigation. Circuits for this purpose have already been devised by others. Particular mention should be made of the work of J. M. Miller and A. Crossley,* who use, among other improvements, a choke coil and grid battery instead of a grid leak; the potential of the grid is thus kept negative over the greater part of the cycle, and the loss due to grid current is considerably reduced.

(3) CONCLUSION.

In the first part of the paper the behaviour of the valve-maintained quartz oscillator has been studied theoretically. The only circuits considered were the two variations of the Pierce circuit, namely:

(i) The plate-to-grid connection, in which the quartz resonator is connected between the plate and the grid; and

(ii) The filament-to-grid connection, in which the resonator is connected between the filament and the grid.

In both cases there was an oscillatory circuit between the plate and the filament.

The quartz oscillator has been represented by a network of admittances, and an equation obtained for the oscillations in the plate circuit. An approximate solution of this equation has been obtained, and expressions have been developed for the frequency and the amplitude of the oscillations in the plate circuit. From these expressions it could be deduced that:

(i) With the plate-to-grid connection:

(*a*) When the capacity C in the oscillatory plate circuit is several times as large as the value C' which would make the natural frequency of the oscillatory circuit equal to the frequency of the quartz resonator, no oscillations take place. As the capacity C is reduced gradually, a value is reached at which oscillations start at a very small amplitude. Further decrease of C is accompanied by increase in the amplitude, until the amplitude reaches a maximum at a value of C which is in general less than 1 per cent above C'. A further small decrease in C produces a rapid decrease in amplitude, until a value is reached at which the oscillations stop suddenly. This value also is greater than C'.

(*b*) The resistance of the oscillatory circuit, the grid leak, and, in general, any resistances or leaks in the circuit, tend to decrease the maximum amplitude of oscillations.

(*c*) A certain amount of capacity, either in the valve or outside, between the grid and the filament, is essential to the maintenance of oscillations. On the other hand, large values of this capacity will make the amplitude small. There is an optimum value which gives maximum power.

(*d*) Any capacity in parallel with the quartz resonator, whether inter-electrode capacity between the plate and the grid, stray capacity between the electrodes of the resonator, or capacity between the leads connecting the resonator to the valve, is always disadvantageous and reduces the power.

(*e*) A large plate conductance and a large amplification factor are beneficial.

(*f*) Any variation of frequency produced by changing the air-gap, the valve or the circuits is in all cases a small fraction only of the response frequency of the resonator when the air-gap is zero, i.e. when the electrodes of the resonator are in contact with the quartz crystal.

(*g*) When the capacity C is gradually decreased from a large value, the frequency increases slowly at first, then more and more rapidly, until the sudden cut-off of the oscillations.

(*h*) The greater the conductance of the grid leak, the greater the frequency.

(*j*) The variation of frequency for a given change of C is greater with large grid conductances than it is with small grid conductances.

(ii) With the filament-to-grid connection:

(*a*) When the capacity C in the plate circuit is zero, oscillations are weak or do not take place at all. As the capacity is gradually increased the amplitude of oscillations increases gradually, and reaches a maximum at a value of C which is, in general, less than 1 per cent below C'. A further small increase of C produces a rapid decrease in amplitude, until a value of C, also smaller than C', is reached, at which the oscillations stop suddenly.

(*b*) The resistance of the oscillatory circuit, the grid leak, and, in general, any resistances or leaks in the circuit, tend to decrease the maximum amplitude of oscillations.

(*c*) A certain amount of capacity, either in the valve or outside, between the grid and the plate, is essential to the maintenance of oscillations, but when this capacity is very large no oscillations take place. There is an optimum value of this capacity, which gives maximum power.

(*d*) Any capacity in parallel with the resonator, either in the valve or outside, reduces the power.

---

* See Reference (8).

(*e*) The frequency is always lower than the frequency in the plate-to-grid connection, but it is never as low as the response frequency of the resonator.

(*f*) Any variation of frequency produced by changing the air-gap, the valve or the circuits is in all cases a small fraction only of the response frequency of the resonator for zero air-gap.

(*g*) When the capacity C is gradually increased from a small value, the frequency decreases slowly at first, then more and more rapidly, until the sudden cut-off of the oscillations.

(*h*) The greater the conductance of the grid leak, the lower the frequency.

(*j*) The variation of frequency for a given change of C is greater with large grid conductances than it is with small grid conductances.

The experimental investigation has confirmed all the deductions made above, for each type of connection, with one exception. It has been found that addition of a grid leak of a suitable value may increase the amplitude of oscillations. The reason may be that the grid leak tends to keep the mean potential of the grid at the most favourable point on the characteristic curve of the valve.

This work was carried out under the auspices of the Radio Research Board, to whom thanks are due for permission to publish it. The author also wishes to thank Dr. D. W. Dye for his constant help and encouragement throughout the investigation.

HIGH-FREQUENCY RESISTANCE MEASUREMENT BY THE USE OF A VARIABLE MUTUAL INDUCTANCE.*

By W. JACKSON, M.Sc., Student.

(*Paper first received* 20*th August, and in final form* 21*st October,* 1929.)

SUMMARY.

The paper deals with a method of high-frequency resistance measurement employing a variable mutual inductance. The sources and magnitude of the errors likely to occur are dealt with mathematically. The results of coil resistance measurements are given and compared with the calculated values of resistance and with the results obtained by the "resistance variation" method. The application to condenser resistance measurement is considered.

(1) INTRODUCTION.

The subject of high-frequency resistance measurement has received considerable attention and it offers many difficulties. Of the several methods of coil resistance measurement which have been developed the "resistance variation" method has received most consistent application, mainly by virtue of its simplicity. The serious disadvantage of the method lies in the fact that the circuit resistance measured gives the combined resistance of the coil and the variable tuning condenser. If the coil resistance is to be accurately determined a condenser of known power factor is therefore a necessity. Since a variable condenser of known power factor at high frequency is not readily obtainable, the results are always liable to give a value of resistance in excess of the true coil resistance required.

The present paper deals with a method of high-frequency resistance measurement suggested by E. B. Moullin,† by which the coil resistance can be determined independently by use of a variable mutual inductance. A simple modification of the circuit connections provides a method of condenser resistance measurement. Although the procedure is different, this latter method closely resembles a bridge previously used by A. Campbell for measurements at acoustic frequencies and known as the "Campbell sifter." The method of coil resistance measurement is, however, quite distinct from that of the Campbell bridge, since the condenser employed is outside the measuring circuit and is used only for tuning purposes.

The early part of the paper consists of a theoretical discussion of the method of coil resistance measurement and of the sources of error which are liable to occur. The later part gives a description of the experimental work carried out, together with a statement of the results obtained, and closes with a brief consideration of the method of condenser resistance measurement.

(2) THEORY OF THE METHOD.

Consider the circuit shown in Fig. 1. L_1 represents a coil the resistance R_1 of which is to be measured. C is a variable condenser forming with L_1 a resonant circuit coupled to a source of continuous oscillations, generating a current of frequency $\omega/(2\pi)$, by means of the small coupling coil L_3. L_2 is a coil whose coupling to L_1 can be varied and which forms with L_1 a variable mutual inductance M, in which the self and mutual inductive effects are in opposition. R is a potentiometer of resistance wire in series with the L_1CL_3 circuit, while V is an indicator for measuring the potential between the points A and B.

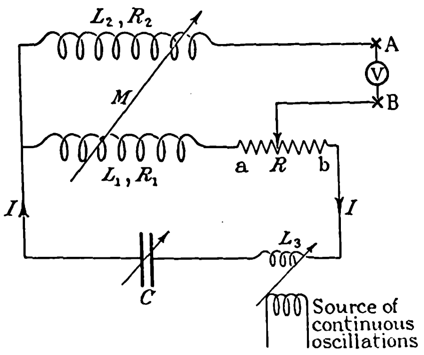

FIG. 1.

Let a current I of frequency $\omega/(2\pi)$ be caused to circulate in the circuit L_1CL_3 by tuning to the generator frequency. Provided that the indicator V has an infinite resistance, no current flows in the circuit L_2AB and the voltage between the points A and B may be written

$$V = \left\{R_1 + j(L_1 - M)\omega\right\}I$$

for the case in which the potentiometer tap is at "a."

Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† "Radio-Frequency Measurements," p. 185.

As M is varied the voltage V passes through a minimum value V_1 for $M = L_1$, when

$$V_1 = R_1 I \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

For this value of M the insertion between the points "a" and B of a pure resistance R increases the voltmeter reading to a value V_2

where $$V_2 = (R + R_1)I \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Provided that I has been constant, equations (1) and (2) enable the unknown resistance R_1 to be determined in terms of V and R. It is preferable to vary R through a series of values and to plot a curve connecting V and the added resistance R. The curve ought to be a straight line, as in Fig. 2, having an intercept OR_1 along the R axis equal to the unknown resistance R_1. This reduces the error which a single reading might entail. If the current I is accurately known the value of R_1 may be checked as OV/I.

The application of this method to the determination of coil resistance at high frequency is, however, complicated by the self and mutual capacities which are always associated with mutual inductances. As the frequency rises these capacities become of increasing importance and seriously modify the simple expression for the minimum voltage given by equation (1).

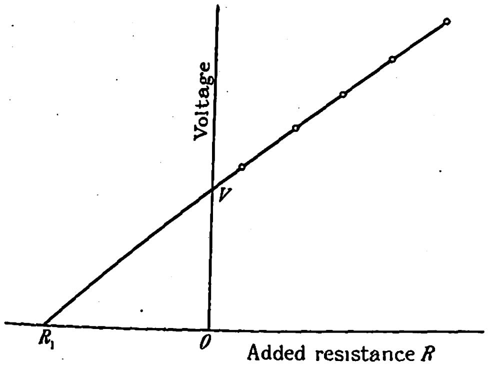

FIG. 2.

The self and mutual capacities of two coupled coils are distributed quantities the distribution of which varies with the nature of the individual coils and with their relative position. It is necessary, for simplicity, to represent these distributed quantities by lumped or concentrated capacities connected across the ends of the coils. While the current distribution in the various parts of the circuit to be considered may be seriously modified by earth capacity effects, it is difficult to allow for their effect since they are not so much a property of the circuit itself as of its position in relation to surrounding bodies and of its potential distribution. These effects, therefore, cannot be considered, but it is of importance to reduce them as much as possible by suitable circuit arrangement and careful earthing.

Representing the self-capacities of L_1 and L_2 by C_1 and C_2 and their mutual capacity by C_{12}, the circuit of Fig. 1 is given in diagrammatic form by Fig. 3.

The current I passing through the condenser C, and measured by the insertion of a thermo-ammeter in close proximity to C, is now the terminal current of L_1 and includes the current passing through C_1 and the other distributed capacities.

The required voltage between A and B, for a known input current I, may be derived as the vector sum of the voltages between AD and DB.

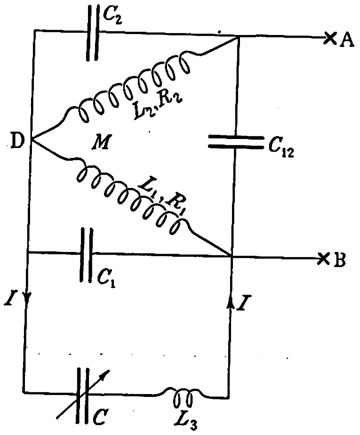

FIG. 3.

The potential difference existing between the terminals A and D of the secondary coil L_2 may be written

$$V_S' = (\sigma + jM'\omega)I \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where M' is the effective mutual inductance between L_1 and L_2, including the effects of self and mutual capacity, and σ an impurity term for which these capacities are responsible.

In an analysis of the capacity effects in standard mutuals Butterworth * has shown that for the case in which the mutual effect opposes the self-inductance, as applies in the present investigation, the circuit of Fig. 3 may be replaced by the simple circuit of Fig. 4, where R_1', R_2', L_1' and L_2' represent the effective resistances and inductances of the primary and secondary coils respectively.

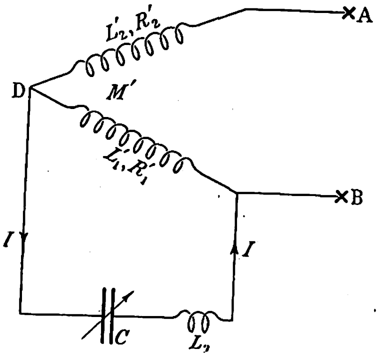

FIG. 4.

---

* *Proceedings of the Physical Society of London*, 1921, vol. 33, p. 312.

R_1' and L_1' are given by the expressions

$$R_1' = R_1\left[1 + 2\omega^2\left\{C_1L_1 + C_{12}(L_1 - M)\right\}\right]$$

$$L_1' = \left[L_1 + \omega^2\left\{C_1L_1^2 + C_2M^2 + C_{12}(L_1 - M)^2\right\} - (C_1 + C_{12})R_1^2\right]$$

The effective mutual inductance M' and the impurity σ may be expressed thus:—

$$M' = M + C_{12}R_1R_2 + \omega^2\left\{C_1L_1M + C_2L_2M - C_{12}(L_1 - M)(L_2 - M)\right\}$$

$$\sigma = \omega^2\left[C_1R_1M + C_2R_2M - C_{12}\left\{R_1(L_2 - M) + R_2(L_1 - M)\right\}\right]$$

The general expression for the potential difference between the points A and B, due to the terminal current I, is therefore

$$\begin{aligned} V' = I\Big[&R_1\left\{1 + 2\omega^2\left\{C_1L_1 + C_{12}(L_1 - M)\right\}\right\} - \omega^2\left\{C_1R_1M + C_2R_2M - C_{12}\left\{R_1(L_2 - M) + R_2(L_1 - M)\right\}\right\}\Big] \\ &+ j\omega I\Big[L_1 + \omega^2\left\{C_1L_1^2 + C_2M^2 + C_{12}(L_1 - M)^2\right\} - (C_1 + C_{12})R_1^2 \\ &\quad - M - C_{12}R_1R_2 - \omega^2\left\{C_1L_1M + C_2L_2M - C_{12}(L_1 - M)(L_2 - M)\right\}\Big] \quad \ldots \quad (4) \\ = I&(a + jb) \quad \ldots \quad (5) \end{aligned}$$

The voltage indicated on a voltmeter of infinite resistance connected across AB is therefore

$$V = I\sqrt{(a^2 + b^2)}$$

This voltage will be a minimum with respect to variations in M when

$$\frac{d}{dM}(a^2 + b^2) = 0$$

Provided that the applied frequency $\omega/(2\pi)$ does not approach the natural frequency of the primary or secondary coils, the value of M, to the first order of small quantities, giving minimum value of $(a^2 + b^2)$, is

$$M = L_1(1 + L_1C_2\omega^2 - L_2C_2\omega^2)^* \quad . \quad . \quad . \quad (6)$$

which is also the condition that the reactive component b is zero.

On substituting this value of M in the expression (4) for V, we obtain

$$V_{min.} = IR_1\left\{1 + L_1C_1\omega^2 - (R_2/R_1)L_1C_2\omega^2 + (L_2 - L_1)C_{12}\omega^2\right\} \quad . \quad (7)$$

The effect of self-capacity in the primary coil L_1, of which the resistance R_1 is required, is thus to increase the apparent value of resistance indicated by the voltmeter reading; that of the secondary self-capacity to decrease it and that of the mutual capacity to increase it, since L_2 must of necessity be greater than L_1 in order to give a mutual inductance at least equal to L_1.

The effect of secondary self-capacity may be reduced by the use of a coil of low resistance R_2. Reduction of the secondary inductance L_2, in necessitating a closer coupling between the coils for provision of the required mutual inductance M, tends to increase the mutual capacity C_{12}.

(3) EFFECT OF DIRECT INDUCED VOLTAGE IN THE SECONDARY COIL.

In injecting an e.m.f. of the desired frequency $\omega/(2\pi)$ into the resonant circuit L_1CL_3, by coupling to the generator magnetically, care must be taken to avoid the injection of a direct induced voltage from the oscillator into the secondary coil L_2. If the circuit L_1CL_3 be tuned to the generator frequency, as will be the case in order to obtain as large a working current as possible, the current I will be in phase with the injected voltage, and therefore lagging 90° behind the generator current. The resistance-drop in L_1 is in antiphase with the current I and leads the oscillator current by 90°. An induced voltage in the secondary coil L_2, which will be approximately 90° out of phase with the generator current, will hence be in phase or in antiphase with the drop R_1I recorded on the voltmeter at the adjustment for minimum reading, depending on the relative directions of winding of the coils L_2 and L_3, and will thus cause the apparent resistance to be too high or too low. The presence of such a leakage e.m.f. may be detected by reversing the connections of the coupling coil so as to reverse its phase relative to the required drop R_1I.

This effect can be prevented only by completely screening the oscillator and the leads from the coupling coil L_3 to the measuring circuit.

By coupling the circuit to the oscillator by means of a resistance potential-divider, any leakage e.m.f. will be in phase quadrature with the intentional e.m.f. and will therefore be of very little importance.

(4) THE EFFECT OF HARMONICS IN THE WORKING CURRENT.

In the previous discussion it has been assumed that the current I was sinusoidal. The error introduced by the presence of harmonics may be investigated by representing the current by $I \sin \omega t + N \sin n\omega t$. This leads to serious mathematical complication unless it is accepted that minimum voltage occurs between A and B when the reactive component of the expression given in equation (5), after the effect of harmonics has been allowed for, is zero.

In this case the minimum voltage between A and B is given by the expression

$$\begin{aligned} V_{min.} &= \sqrt{\left[I^2R_1^2\left\{1 + L_1C_1\omega^2 - (R_2/R_1)L_1C_2\omega^2 + C_{12}\omega^2(L_2 - L_1)\right\}^2 + N^2R_1^2\left\{1 + n^2L_1C_1\omega^2 - n^2(R_2/R_1)L_1C_2\omega^2 + n^2C_{12}\omega^2(L_2 - L_1)\right\}^2\right]} \\ &= R_1\sqrt{(I^2 + N^2)}\left[1 + \left\{L_1C_1\omega^2 - \frac{R_2}{R_1}L_1C_2\omega^2 + C_{12}\omega^2(L_2 - L_1)\right\}\frac{I^2 + n^2N^2}{I^2 + N^2}\right] \\ &= R_1\sqrt{(I^2 + N^2)}\left[1 + \left\{L_1C_1\omega^2 - \frac{R_2}{R_1}L_1C_2\omega^2 + C_{12}\omega^2(L_2 - L_1)\right\}\left\{1 + (n^2 - 1)\frac{N^2}{I^2 + N^2}\right\}\right] \end{aligned}$$

---

* See Appendix.

In order for a second harmonic to double the error due to self and mutual capacity, the ratio N/I would have to be $1/\sqrt{2}$ and for the nth harmonic $1/\sqrt{(n^2-2)}$.

From the above it would appear that the error due to harmonics is not likely to be serious in any case in which the circuit L_1CL_3 is tuned to the fundamental frequency of the oscillator.

(5) Experimental Results.

It is evident that unless care is taken in the construction of the mutual inductance, having as primary the coil of which the resistance is required, serious errors may be incurred. The provision of a suitable mutual inductance is a difficult matter, especially as very fine variation is necessary in order that there may be no difficulty in adjusting for minimum voltage between A and B (Fig. 1). The mutual inductance used consisted of two cylindrical single-layer coils wound on paxolin formers mounted coaxially end to end, the primary coil L_1 being fixed and the secondary L_2 movable. A coarse and a vernier adjustment were employed for varying the position of L_2 axially relative to L_1, while a clamping screw enabled the coil L_2 to be fixed when the final adjustment of M was completed. In order to reduce the mutual capacity between the coils the common point D was obtained by joining the adjacent ends of the coils, thus keeping the high-potential ends as far apart as possible.

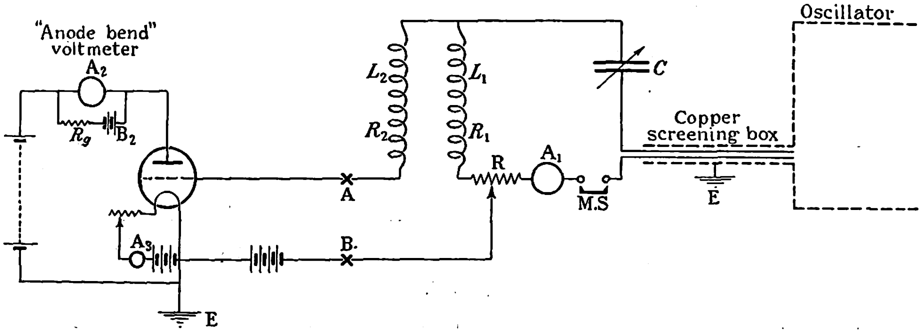

Fig. 5.

The most suitable voltage indicator for the purpose is the anode-rectification type of thermionic voltmeter, since, by the use of negative grid bias, grid current can be prevented for the range of voltage it is desired to measure, thus ensuring an infinite resistance between the points A and B. Such a voltmeter can readily be calibrated to measure high-frequency voltages accurately from 0·5 to 1·5 volts. If the resistance to be measured is of the order of 1 or 2 ohms the current I must be appreciable—up to 0·5 ampere—for accurate indication of the voltage, if the added complication of amplifiers is to be avoided. With such currents flowing, the voltage across L_1 will be considerable and, unless M is carefully adjusted, the indicating instrument may be damaged.

The provision of current outputs of the above order does not offer any difficulty with a valve oscillator, but it is important that the entire oscillator, together with the leads to the measuring circuit, be completely screened in order to prevent direct induced voltage into either the secondary of the mutual inductance or the voltmeter circuit. As previously mentioned, this could be checked by reversing the connections of the coupling coil and noting whether this produced an alteration in the apparent resistance of the coil L_1.

The oscillator was enclosed in a copper box having a lid with deep overlaps, while the leads to the measuring circuit were passed through a copper tube soldered into the side of the box. Currents up to 1·0 ampere were obtainable at resonance in the circuit L_1CL_3.

The potentiometer R was of Eureka resistance wire arranged non-inductively by bringing back the return lead close to the potentiometer wire, and was provided with 8 tappings in a total resistance of approximately 2·0 ohms.

The complete circuit connections showing the earthed points are given in Fig. 5. M.S. was a mercury cup switch for opening and closing the circuit L_1CL_3 when required; A_1 a thermo-ammeter for measuring the current in the L_1CL_3 circuit and A_2 a micro-ammeter in the voltmeter plate circuit, the zero deflection being balanced out by a small battery B_2 in series with a high resistance R_g round the micro-ammeter circuit.

Table 1.

	Primary coil	Secondary coil

Self-capacity ..	By direct measurement $C_1 = 4\cdot0\mu\mu$F	Natural wavelength when erected on base of mutual = 210 m $C_2 = 7\cdot0\ \mu\mu$F

In order to prevent hand-capacity effects during the measurements, an earthed electrostatic screen, consisting of a number of parallel wires joined together at one end, was erected between the observer and the measuring circuit. To enable the mutual inductance to be varied with the screen in position, the control rod of the mutual was made of considerable length and passed through the screen.

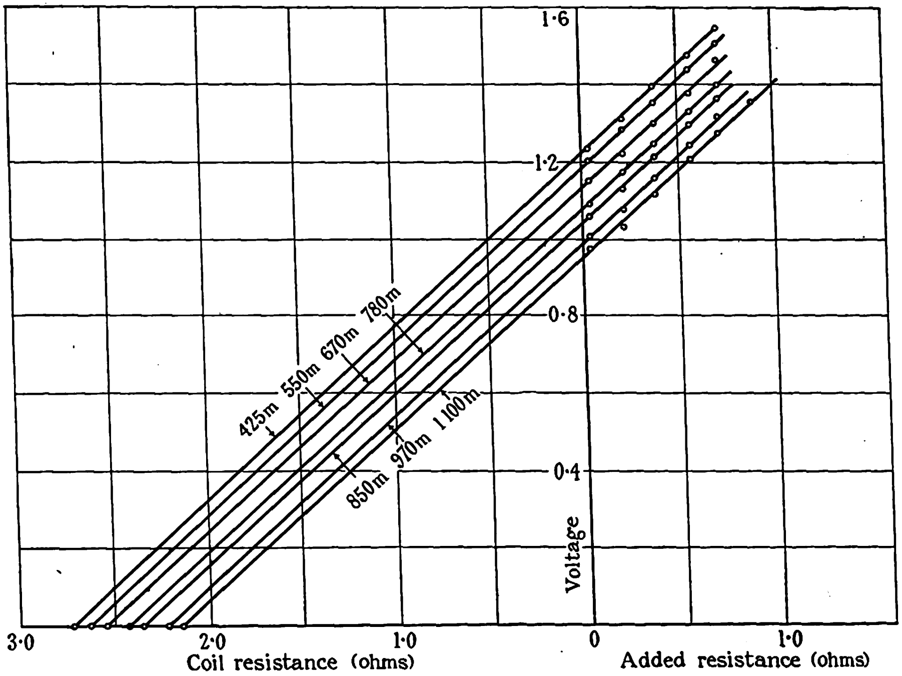

FIG. 6.

(A) The results of a series of measurements, taken over a wavelength range of 1 100 m to 425 m, using this mutual inductance are shown in Fig. 6. The curves connecting voltage between the points A and B, and added resistance R, when produced backwards to meet the resistance axis, give the apparent resistance R_1 of the primary coil L_1 at the several frequencies.

The constants of the primary and secondary coils of the mutual inductance, as measured independently, are shown in Table 1.

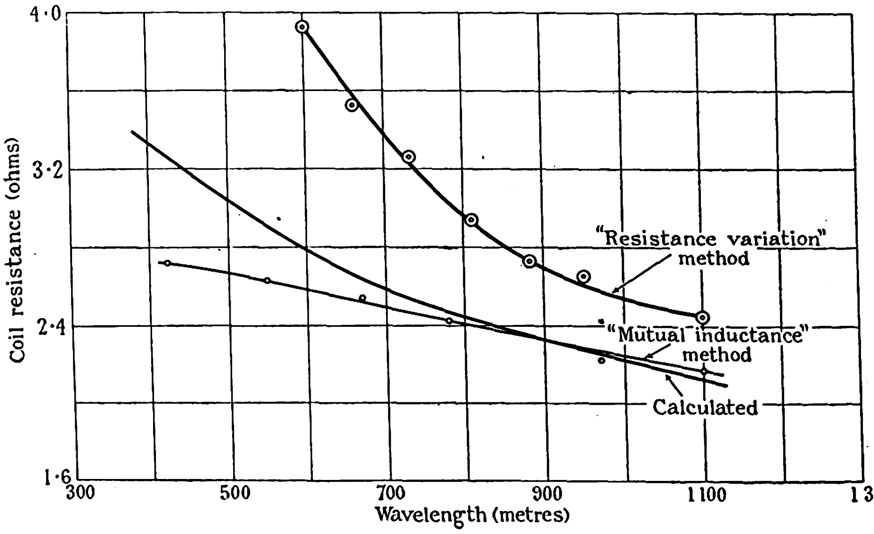

FIG. 7.

The large inductance of the secondary coil was necessary in order to provide the required value of mutual inductance without too close proximity between the primary and secondary coils. When adjusted to give a minimum voltmeter reading the ends of the coils L_1 and L_2 were approximately 1 cm apart. As the frequency was increased it was necessary, in providing the requisite value of M for minimum voltmeter reading, to reduce the coupling between the coils, indicating that capacity effects were present, an effect consistent with equation (6). This became pronounced in the region of 400 m.

Throughout the measurements the current I in the resonant circuit L_1CL_3 was adjusted to 0·43 ampere.

The apparent resistance R_1 deduced as OV/I (see Fig. 2) agrees to within a few per cent with the derived value OR_1.

A comparison of the above results with the calculated values of resistance using Butterworth's theoretical formula for short single-layer coils is obtained from the curves of Fig. 7. The theoretical formula mentioned is

$$R_f = R_0\left\{1 + F + uG\frac{d^2}{D^2}\right\}$$

where R_f is the resistance at frequency f cycles per second, R_0 is the resistance to direct current, $(1 + F) = \frac{1}{4}(\sqrt{2}z + 1)$, $G = \frac{1}{8}(\sqrt{2}z - 1)$, $z = \pi d\sqrt{(2f/\rho)}$, d is the wire diameter and D the pitch of the turns, each in centimetres. The factor $u = 3\cdot29 + b/a$, where b is the length of the coil and a its radius.

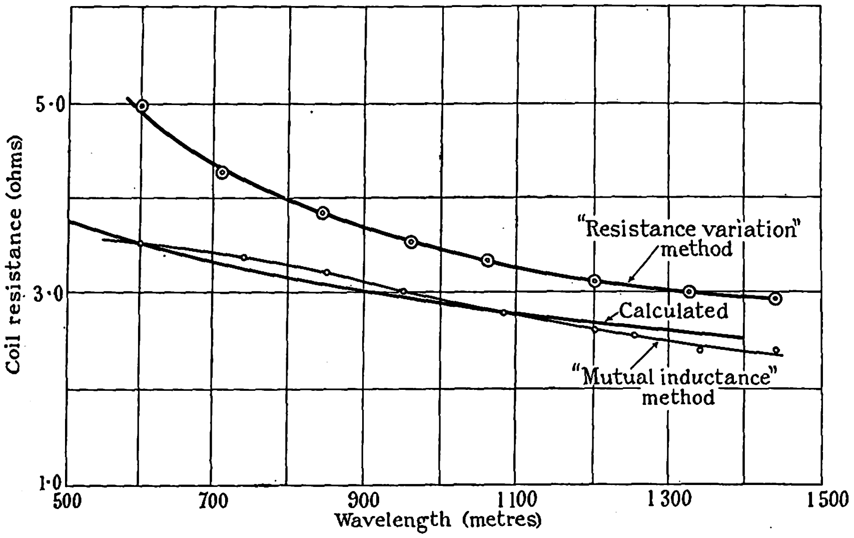

FIG. 8.

TABLE 2.

	Primary coil	Secondary coil

Self-capacity ..	By direct measurement $C_1 = 4\cdot5\ \mu\mu F$	Natural wavelength when erected on base of mutual = 335 m $C_2 = 8\cdot2\ \mu\mu F$

At the longer wavelengths there is close agreement between the two resistance curves, with the value of resistance as measured by the mutual-inductance method slightly in excess of the calculated values. This is to be expected, since Butterworth's formula is based purely on a consideration of the eddy-current losses in the coil and does not include the effect on the apparent coil resistance of either the capacity between turns or the high-frequency dielectric losses in the coil former. At the shorter wavelengths, however, there is an increasing tendency for the mutual-inductance method to underestimate the coil resistance, indicating that capacity effects, in particular that due to secondary coil self-capacity, are becoming of importance in affecting the derived values of resistance. An estimate of the effect of the self-capacities C_1 and C_2 may be obtained from a consideration of equation (7). By use of the measured coil constants it can be shown that C_1 and C_2 may be expected to produce a net reduction in apparent coil resistance of 1·5 per cent at 1 000 m and 7·5 per cent at 400 m, although this does not take into consideration any compensating effect of mutual capacity, which would become of importance if C_{12} exceeded 2 μμF or 3 μμF.

The results of high-frequency resistance measurements on the primary coil L_1 when the resistance variation method is employed are also given in Fig. 7. The serious discrepancy between these resistance values and those obtained by the mutual-inductance method is, in part, due to this under-estimating effect. The correction is, however, much less than the difference to be accounted for, and it is therefore justifiable to account for this difference mainly by the unknown resistance of the condenser used in the resonant circuit of the resistance-variation method. This serves to show how important the condenser resistance, if unknown, may be as a source of error in the latter method.

(B) Table 2 gives the constants of a pair of coils wound to replace the primary and secondary of the previous mutual inductance for the purpose of further checking the accuracy of the method. The results of resistance measurements on the primary coil by the mutual inductance and resistance variation methods, together with the calculated values, are shown in Fig. 8.

The resistance values obtained by the mutual method are again in close agreement with the calculated values, but appreciably low compared with the resistance variation measurements. An estimation of the effect of primary and secondary coil self-capacities on the resistance values obtained by the mutual method shows them to be responsible for a net reduction in apparent resistance of 4·5 per cent at 1 500 m and 15·0 per cent at 700 m. It is worthy of note, however, that a mutual capacity of 6 $\mu\mu$F would be sufficient to compensate entirely for this 15 per cent reduction at 700 m by the introduction of an equal error of reverse sign. While such a high value of C_{12} is not to be expected in the coils of the mutual themselves, since at the setting for minimum voltmeter reading the adjacent ends of the coils L_1 and L_2 were more than 1 cm apart and these ends were joined, it may easily be provided in the input capacity of the voltmeter. This capacity would exist between the points A and B (Fig. 3), and although the valve used in the voltmeter was a V24 low-capacity valve it is unlikely that its capacity would be less than 5·0 $\mu\mu$F.

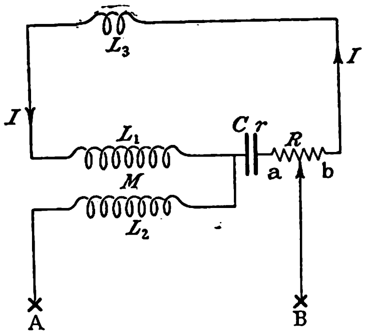

FIG. 9.

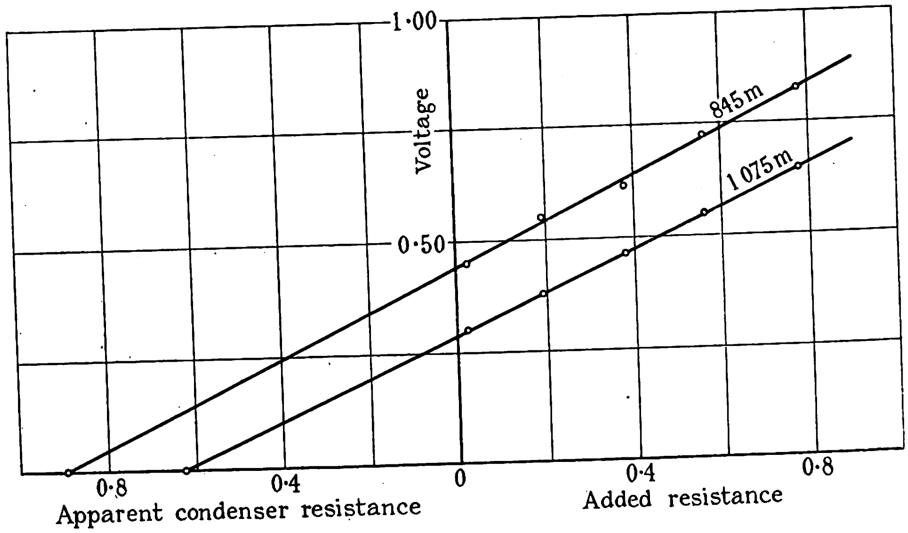

FIG. 10.

(6) CONCLUSIONS.

The recorded work serves to demonstrate that the method is capable of giving results which compare favourably with the calculated values of coil resistance at wavelengths well removed from the natural wavelength of the secondary coil. At wavelengths approaching this the small self and mutual capacities inherent in the mutual inductance are capable of introducing errors which, while to some extent compensating, may be far from inconsiderable. These errors may, however, be reduced by careful design of the mutual inductance and may be estimated with reasonable accuracy. As an offset to this disadvantage, the method possesses the advantages that no knowledge of the tuning condenser power factor is necessary, and there is no difficulty in manipulation or in indication of the balance condition.

(7) APPLICATION TO CONDENSER RESISTANCE MEASUREMENT.*

The system shown in Fig. 1 is readily adapted to the measurement of condenser resistance by a modification of the circuit connections to those of Fig. 9.

The condenser C, the resistance r of which is to be measured, is connected in series with the primary coil L_1 and a small coil L_3 coupled to the oscillation generator. The secondary coil L_2 has one end joined to the common point of L_1 and C, and the other to one terminal A of the voltmeter. The other voltmeter terminal B is taken to the potentiometer R connected in series with the L_1CL_3 circuit.

For a current I of frequency $\omega/(2\pi)$, caused to circulate round the circuit L_1CL_3 by tuning to the generator frequency, the voltage between the points A and B with the potentiometer tap at "a" may be written

$$V = I\left\{r + j\left(M\omega - \frac{1}{C\omega}\right)\right\}$$

As M is varied, the voltage V passes through a minimum value V_1 for $M\omega = 1/(C\omega)$, that is for $M = 1/(C\omega^2)$, when $$V_1 = rI \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

---

* E. B. MOULLIN, *loc. cit.*, p. 145.

For this value of M the insertion of a pure resistance R between the points a and B increases the voltmeter reading to V_2, where

$$V_2 = (r + R)I \quad . \quad . \quad . \quad . \quad . \quad (9)$$

The unknown resistance r may be determined from equations (8) and (9) in terms of V and R, or from a curve connecting V and R obtained by varying R through a series of values.

The curves of Fig. 10 show the results obtained on a large variable air condenser using the mutual inductance, the constants of which are given in Table 1, at wavelengths of 1 075 and 845 m, both well removed from the natural wavelength of the secondary coil. The condenser resistances at these two wavelengths, and for condenser capacities of 1 980 and 1 220 $\mu\mu$F respectively, are thus found to be 0·62 and 0·89 ohm. These values of condenser resistance correspond to condenser power-factors of $2 \cdot 15 \times 10^{-3}$ and $2 \cdot 42 \times 10^{-3}$ respectively.

While it was expected that the power factor would be high, these values seem to be larger than one would justifiably expect in an air condenser.

Avoiding as it does the need for a standard condenser of known power factor, as is required in the comparison methods of condenser-resistance measurement, the method would appear to justify development.

The thanks of the author are due to the Governing Body of the Bradford Technical College for the facilities provided at the College for carrying out the recorded work, and also to Mr. E. B. Moullin, Associate Member, for his interest and for his help in scrutinizing the manuscript.

APPENDIX.

The general expression for the potential difference between the points A and B (Fig. 4), given by equation (4), may be written in the form

$$V = I(a + jb)$$

where

$$a = R_1\left[1 + 2\omega^2\left\{C_1L_1 + C_{12}(L_1 - M)\right\} - \omega^2\left\{C_1M + (R_2/R_1)C_2M - C_{12}\left\{(L_2 - M) + (R_2/R_1)(L_1 - M)\right\}\right\}\right]$$

and

$$b = \omega\left[L_1 + \omega^2\left\{C_1L_1^2 + C_2M^2 + C_{12}(L_1 - M)^2\right\} - (C_1 + C_{12})R_1^2 \right.$$
$$\left. - M - \omega^2\left\{C_1L_1M + C_2L_2M - C_{12}(L_1 - M)(L_2 - M)\right\} - C_{12}R_1R_2\right]$$

Since in the derivation of equation (1), when self and mutual capacities were not taken account of, it was shown that the voltage V was a minimum when M was equal to L_1, it is justifiable in the above, in which the effects of the small capacities C_1, C_2 and C_{12} are allowed for, to consider $(L_1 - M)$ as small compared with either L_1, L_2, M or $(L_2 - M)$, L_2 being necessarily much greater than L_1, and therefore M, in order to provide the required value of mutual inductance with reasonably loose coupling between L_1 and L_2. Hence as C_1, C_2 and C_{12} are of similar magnitude, $C_{12}(L_1 - M)$ may be neglected in comparison with C_1L_1, since $C_1L_1\omega^2$ is itself a small quantity compared with unity, provided that $\omega/(2\pi)$ does not approach the natural frequency of the primary coil. Also, since R_1 and R_2 need not be of sensibly different magnitude, $(R_2/R_1)(L_1 - M)$ may be neglected in comparison with $(L_2 - M)$. Similarly in the expression for b, $C_{12}(L_1 - M)^2$ can be considered to be negligible in comparison with $(C_1L_1^2 + C_2M^2)$, since under the previous condition $\omega^2(C_1L_1^2 + C_2M^2)$ is itself small compared with L_1. Also, provided that the natural frequency of the secondary coil is not approached, $C_{12}(L_1 - M)(L_2 - M)$ may be neglected in comparison with $(C_1L_1M + C_2L_2M)$.

The expressions for a and b therefore reduce to

$$a = R_1\left\{1 + 2\omega^2C_1L_1 - \omega^2C_1M - \omega^2(R_2/R_1)C_2M + \omega^2C_{12}(L_2 - M)\right\}$$
$$b = \omega\left\{L_1 + \omega^2(C_1L_1^2 + C_2M^2) - (C_1 + C_{12})R_1^2 - M - \omega^2(C_1L_1M + C_2L_2M) - C_{12}R_1R_2\right\}$$

that is

$$a = R_1(1 + 2\omega^2C_1L_1 + \omega^2C_{12}L_2) - M\left[R_1\omega^2\left\{C_1 + (R_2/R_1)C_2 + C_{12}\right\}\right]$$
$$b = \omega\left\{L_1 + \omega^2C_1L_1^2 - (C_1 + C_{12})R_1^2 - C_{12}R_1R_2\right\} - M\left[\omega\left\{1 + \omega^2(C_1L_1 + C_2L_2 - C_2M)\right\}\right]$$
$$= \omega\left\{L_1 + \omega^2C_1L_1^2 - (C_1 + C_{12})R_1^2 - C_{12}R_1R_2\right\} - M\left[\omega\left\{1 + \omega^2\left\{C_1L_1 + C_2(L_2 - L_1) + C_2(L_1 - M)\right\}\right\}\right]$$

In the expression for b, $(C_1 + C_{12})R_1^2$ and $C_{12}R_1R_2$ are negligible in comparison with $\omega^2C_1L_1^2$, R_1 and R_2 being small compared with $L_1\omega$. Further, $C_2(L_1 - M)$ is negligible compared with $C_1L_1 + C_2(L_2 - L_1)$.

Hence $$a = \alpha - M\beta \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

and $$b = \eta - M\gamma \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

where
$$\alpha = R_1\left\{1 + 2\omega^2C_1L_1 + \omega^2C_{12}L_2\right\}$$
$$\beta = R_1\omega^2\left\{C_1 + (R_2/R_1)C_2 + C_{12}\right\}$$
$$\eta = \omega L_1(1 + \omega^2C_1L_1)$$
$$\gamma = \omega\left\{1 + \omega^2C_1L_1 + \omega^2C_2(L_2 - L_1)\right\}$$

The voltage $V = I(a + jb)$ will be a minimum with respect to variations in M when

$$\frac{d(a^2 + b^2)}{dM} = 0$$

that is when $$M = \frac{\alpha\beta + \eta\gamma}{\beta^2 + \gamma^2}$$

On substitution for α, β, η and γ,

$$M = \frac{R_1^2\left\{C_1 + (R_2/R_1)C_2 + C_{12}\right\}(1 + 2\omega^2C_1L_1 + \omega^2C_{12}L_2) + L_1(1 + \omega^2C_1L_1)\left\{1 + \omega^2C_1L_1 + \omega^2C_2(L_2 - L_1)\right\}}{R_1^2\omega^2\left\{C_1 + (R_2/R_1)C_2 + C_{12}\right\}^2 + \left\{1 + \omega^2C_1L_1 + \omega^2C_2(L_2 - L_1)\right\}^2}$$

Expanding and neglecting terms of the second order of small quantities—to which

$$R_1^2\left\{C_1 + (R_2/R_1)C_2 + C_{12}\right\}(1 + 2\omega^2C_1L_1 + \omega^2C_{12}L_2)$$

and $$R_1^2\omega^2\left\{C_1 + (R_2/R_1)C_2 + C_{12}\right\}^2$$

in the numerator and denominator respectively belong —this required value of M reduces to

$$\begin{aligned} M &= \frac{L_1\left\{1 + 2\omega^2C_1L_1 + \omega^2C_2(L_2 - L_1)\right\}}{1 + 2\omega^2C_1L_1 + 2\omega^2C_2(L_2 - L_1)} \\ &= L_1\left\{1 - \omega^2C_2(L_2 - L_1)\right\} \\ &= L_1(1 + L_1C_2\omega^2 - L_2C_2\omega^2) \end{aligned}$$

to the first order of small quantities.

The minimum voltage between the points A and B (Fig. 4) is obtained by substituting this value of M in the expression

$$V = I\sqrt{(a^2 + b^2)}$$

Using equation (11) we obtain

$$\begin{aligned} b = \omega L_1(1 + \omega^2C_1L_1) - \omega L_1\Big\{1 &+ \omega^2C_1L_1 \\ &+ \omega^2C_2(L_2 - L_1)\Big\}\left\{1 - \omega^2C_2(L_2 - L_1)\right\} = 0 \end{aligned}$$

to the first order of small quantities.

Hence $V_{min.} = Ia$, where, by equation (10),

$$\begin{aligned} a = R_1(1 &+ 2\omega^2C_1L_1 + \omega^2C_{12}L_2) \\ &- R_1\omega^2\left\{C_1 + (R_2/R_1)C_2 + C_{12}\right\}L_1 \end{aligned}$$

to the first order of small quantities

$$= R_1\left\{1 + \omega^2C_1L_1 - (R_2/R_1)\omega^2C_2L_1 + \omega^2C_{12}(L_2 - L_1)\right\}$$

Hence, finally,

$$\begin{aligned} V_{min.} = IR_1\Big\{1 + L_1C_1\omega^2 &- (R_2/R_1)L_1C_2\omega^2 \\ &+ (L_2 - L_1)C_{12}\omega^2\Big\} \end{aligned}$$

A METHOD OF TESTING CURRENT TRANSFORMERS.*

By W. E. Bruges.

(*Paper first received 15th October, and in final form 19th December, 1929.*)

SUMMARY.

The author outlines a simple method of testing current transformers. The method is an absolute one and does not call for expensive apparatus or rely on the existence of a number of "standard" transformers.

There are two methods commonly in use at present by which current transformers are tested. There is the Silsbee method (Fig. 1) in which the transformer under test is placed in series with a previously calibrated transformer. The "spill" current is measured both in magnitude and in direction, and the error of the transformer under test can be roughly calculated. The spill current represents the vectorial difference between the errors of the two transformers.

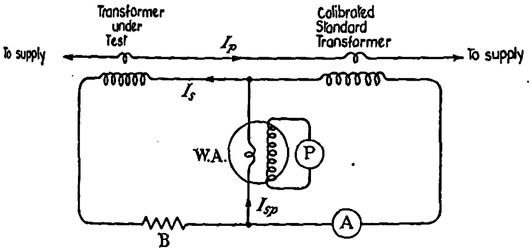

FIG. 1.—Silsbee (spill) method.

A = ammeter.
W.A. = wattmeter used as ammeter.
P = phase-shifter, excited from supply.
B = burden resistance.
I_p = primary current.
I_s = secondary current.
I_{sp} = spill current.
I_{ps} = phase-shifter current.

The other, the "bridge" method, is shown in Fig. 2. It relies on a calibrated condenser and resistances, and is comparatively expensive to arrange. Whilst this method is incapable of dealing with frequencies other than the fundamental, of which the error current may be composed, it possesses the very great advantage that the resistances and condenser may, if desired, be calibrated once and for all for a particular frequency. It is an absolute method. In order to avoid the use of very large shunts, a special transformer may be provided, as shown in Fig. 2. The secondary coil of this transformer should have a very low resistance, and the core should be made of high-permeability iron, such as mumetal, because if the error of this transformer has to be taken into consideration the method is scarcely an improvement on the Silsbee method. The vibration galvanometer will have comparatively large currents passing through it at other frequencies than the fundamental, harmonics, being exaggerated, of course, by the condenser.

The method to be described is shown in Fig. 3 in its simplest form. The transformer to be tested is placed in series with another current transformer having approximately the same ratio. The latter transformer the author proposes to call the balancing transformer, and its primary and secondary windings are placed in series with the primary and secondary windings, respectively, of the transformer under test. A phase-shifter is connected to the secondary terminals of the balancing transformer, or to a tapping, or to a separate winding round this transformer.

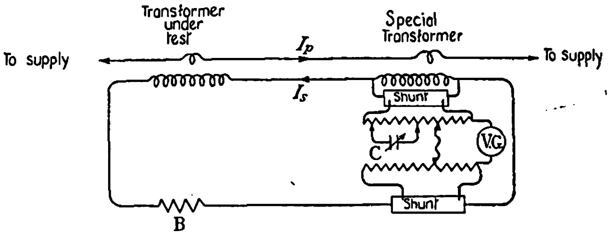

FIG. 2.—Bridge method.

V.G. = vibration galvanometer.
C = condenser.

The phase-shifter is adjusted until the flux in the balancing transformer is reduced to a negligible value, and the current delivered by the phase-shifter is then read. From the reading, the error of the transformer under test can either be directly stated or be very quickly calculated.† It may be shown that the error, referred to the primary, is:

$$\frac{k' - k}{k'} I_p + \frac{k}{k'} \cdot \frac{n}{N} I_{ps} \quad . \quad . \quad . \quad . \quad (1)$$

---

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† Let the error of the transformer under test, referred to the primary, be ϵ.

Then $$\epsilon = I_p - kI_s \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where I_p = primary current;
I_s = secondary current; and
k k', n, N are as given in the text.

When the flux of the balancing transformer has been reduced to zero, we have

$$(n/N)I_{ps} = I_p - k'I_s \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

whence $$I_s = (1/k')[I_p - (n/N)I_{ps}]$$

Substituting in (2), therefore,

$$\epsilon = I_p - (k/k')[I_p - (n/N)I_{ps}]$$
$$= [(k' - k)/k']I_p + (k/k')(n/N)I_{ps}$$

It must be borne in mind that ϵ, I_p, I_s and I_{ps} are all vector quantities.

where k = desired ratio (secondary to primary) of the transformer under test;
k' = turn ratio (secondary to primary) of the balancing transformer;
I_p = primary current;
I_{ps} = current delivered by the phase-shifter;
n = number of turns round the balancing transformer which are in series with the phase-shifter;
N = number of primary turns on the balancing transformer.

The two terms in the above formula must be added vectorially. It will be noticed that when $k = k'$ and $n/N = k$, the error becomes kI_{ps}. It will often be convenient to arrange for this to be the case, but it is not always possible, for instance when it is desired to operate a transformer in a protective circuit on a 3-phase line and the transformer has an odd ratio which is some multiple of $\sqrt{3}$.

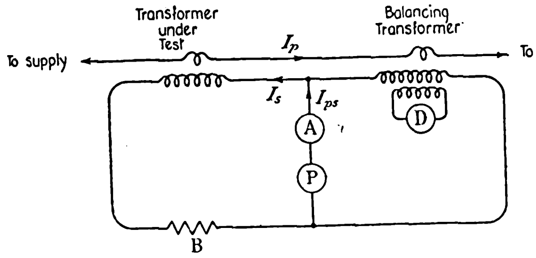

FIG. 3.

D = detector (milliammeter or galvanometer).

In order to ascertain when the flux in the core of the balancing transformer has been reduced to a negligible value, a detector—which may be a milliammeter or a galvanometer—is placed in series with a number of turns taken round the core of the balancing transformer. The phase-shifter is adjusted until the detector reads zero or a minimum value.‡

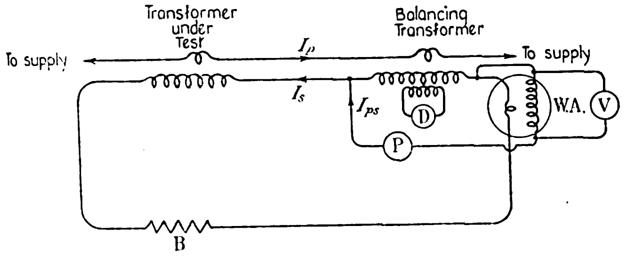

FIG. 4.

V = voltmeter.

The current delivered by the phase-shifter can be read by means of an ammeter placed in its output circuit; but generally it is desired to know both the magnitude and the direction of the current, and a wattmeter may then be used in conjunction with a voltmeter, as shown in Fig. 4, or in conjunction with an ammeter, as shown in Fig. 5. The ammeter reads the total current, and the wattmeter the component which is in phase with the secondary. This is shown vectorially in Fig. 6.

When the flux in the balancing transformer has been reduced, as described, the reactive effect of the balancing transformer will be negligible and the burden of the transformer under test may be calculated in the usual way, the windings of the balancing transformer being considered to be purely a resistance. When the burden is entirely resistive, it will usually be sufficient to multiply the secondary current by the total resistance of the secondary circuit, including that of the balancing transformer. This gives the voltage which has to be supplied by the transformer under test.

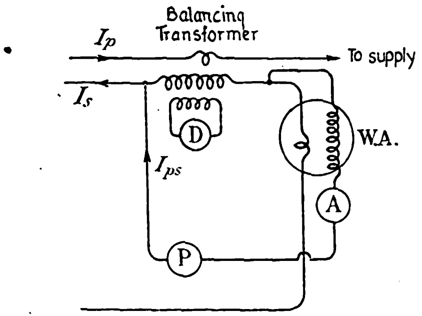

FIG. 5.

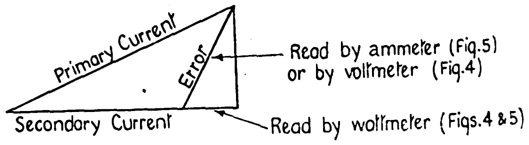
Further, since the effect—and therefore the sum—of the ampere-turns on the balancing transformer is a minimum, the current supplied by the phase-shifter will represent the difference between the primary and secondary ampere-turns of this transformer. As the windings of the balancing transformer are in series with the windings of the transformer under test, it follows that the current supplied by the phase-shifter also represents the difference between the primary and secondary ampere-turns on the latter transformer. An allowance must be made if the desired ratio of the transformer under test differs from the turn ratio of the balancing transformer, and this will be taken care of if the formula given above is used.



Primary Current
Error
Read by ammeter (Fig.5) or by voltmeter (Fig.4)
Secondary Current
Read by wattmeter (Figs.4 & 5)

FIG. 6.

It is occasionally advantageous to connect the phase-shifter to a separate tapping, or even to a separate winding on the balancing transformer. This may occur if it is desired to increase the current so that it may be more easily read by the instruments at one's disposal. A close coupling between the windings will then be advisable. Generally speaking, the test may be carried out with any current transformer having a known number of turns—the detector winding being wound round the outside. It would be more convenient to provide a tapped balancing transformer having a large core and low-resistance windings. One such transformer would be used for many

---

‡ The number of turns in series with the detector for maximum sensitivity should be N_d, given by

$$N_d/N_b = \sqrt{R_d/R_b}$$

where N_b = number of secondary turns on the balancing transformer;
R_d = resistance of detector circuit; and
R_b = resistance of main secondary circuit of the two transformers = total burden resistance.

ratios and could be kept for the purpose. For accurate tests it will then be possible to make the first term in formula (1) as small as possible. If the resistance of the windings is made small, the burden can be more conveniently adjusted by an external resistance.

A very small error of the second order is introduced if a separate transformer is used to excite the wattmeter current coil, or if the current coil is not part of the burden itself. This error is usually negligible, but it can, where necessary, be calculated from a separate test. It is thought that it would generally be preferable not to include the wattmeter current-coil as part of the burden, and to short-circuit this coil while the detector reading is being reduced to zero; if this is not done, its reactance and resistance must be known.

It will be seen that although the wave-form of the phase-shifter is important, it is not necessary that it should possess a degree scale or be calibrated in any way.

It will generally be found impossible to reduce the detector reading absolutely to zero, owing to the harmonics in the magnetizing current of the transformer under test. These harmonics may be supplied separately by other phase-shifters. Whilst it is generally necessary to observe only the fundamental component of the error of a current transformer, nevertheless it is interesting to be able also to observe what differences occur due to harmonics. With well-made transformers these differences should be small. It should be mentioned that if the primary current is sinusoidal, the secondary current will be very nearly so, unless the magnetizing current is inordinately large; hence the voltage to be supplied by the transformer, which is usually the product of the current and the resistance of the circuit (the reactance being kept small), will also be nearly sinusoidal. Therefore the magnetizing current itself may be far from sinusoidal; its wave-form may be worked out approximately from flux curves, and the third harmonic will usually be seen to predominate.

It is worth noticing that the vector diagram of a current transformer may be drawn as ABCD in Fig. 7, where AB = secondary ampere-turns, CA = primary ampere-turns, and BC is the error in ampere-turns. Assuming a constant volt-ampere burden, BC will move, as the reactance or capacity of the secondary circuit is altered, on a circle with centre C. BCD is a right-angled triangle, CD representing the true magnetizing current and BD the iron losses. If AB is produced to E, DBE will represent the angle whose cosine is the power factor of the secondary circuit.

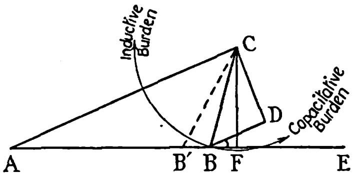


FIG. 7.

In formula (1) above, if $k = k'$, BC $= I_{ps}$, and BF is read from the wattmeter WA (see Figs. 4 and 5), where the point F is found by dropping a perpendicular CF on AE. If k is not equal to k', there will be another point B′ in AB. The wattmeter WA reads B′F, and B′C $= I_{ps}$. Generally we are able to arrange that the reactance in the burden circuit is negligible, at any rate for test purposes; then, of course, the angle DBE becomes zero and the point D lies in AB produced.

If the phase-shifter incorporates a degree scale, use may be made of this for checking results and for noticing the effect of reactance in the circuit.

DISCUSSION ON

"THE CONSTRUCTION OF THE 'GRID' TRANSMISSION SYSTEM IN GREAT BRITAIN." *

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE, AT LIVERPOOL, 4TH NOVEMBER, 1929.

Mr. B. Welbourn: In designing the grid, the engineers of the Board have based it on the experience of the whole world. The extent of their inquiries is shown by the figures given in the paper. Whatever the experience lying behind the design and intended method of operation, each country has its own peculiar difficulties, and I venture to suggest how a few of these may be overcome on grid schemes which have not yet been completed. Valuable time and some expense would be saved if the preliminary surveys carried out by the Board could be done with such accuracy that the absolute positions of the towers could be determined and pegged out, thus avoiding a detailed re-survey by the contractors. Another difficulty which is commonly experienced by the Board, the Post Office, power companies, municipalities and others with overhead lines to erect, is that of obtaining wayleaves. In England we are individualists and do not like to interfere with the rights of property; but there comes a time when people cannot do absolutely what they like with their own property, because public utilities are being held up. There are two possible methods of dealing with the situation other than the persuasive method so far adopted by the Board. The Board have in their hands a weapon which might be used more freely than at present, in the right conferred on the Ministry of Transport to hold inquiries with a view to settling these questions. There has been a natural reluctance at the commencement of a new national scheme to make use of this power, but, when owners adopt the attitude that, although they are willing that a tower should be erected on their property, they will not allow its erection until they are forced, then it is time to adopt other methods, and I think that the Board might usefully consider arranging with the Ministry of Transport to hold monthly courts of inquiry in each grid area, so that all difficult cases could be brought before the court and disposed of in a regular way. My opinion is that this method would be so effective that there would be no need to resort to more drastic methods; but, should the proposed scheme be tried and prove a failure, then it would seem that the Government would have to ask Parliament to pass a one-clause Act giving the Board much more drastic powers in regard to wayleaves. The question of the life of steel-cored aluminium conductors under the climatic conditions existing in certain areas in this country has obviously considerably exercised the minds of the authors, and they have come to the conclusion that a life of 25 years can be depended upon. Strong evidence in support of this view is afforded by the behaviour of similar conductors in the worst industrial atmospheres in France and in and around Pittsburg in the United States. The case of Pittsburg was carefully examined about 18 months ago, with reassuring results. The examination showed that, with a galvanized-steel core and a single layer of aluminium wire surrounding it, the steel core was entirely protected against corrosion. On the grid the main conductors have two layers of aluminium surrounding the galvanized-steel centre while, in the case of the earth wire, the galvanized-steel core is compounded before the single layer of aluminium is laid on it, so that it is evident that, with the precautions taken and the experience gained elsewhere, there is no need to fear that the core will be attacked by the atmosphere, bad though it is in some districts. The authors do not indicate any way of dealing with vibration troubles with the conductors, if and when they arise. Our inquiries in the United States indicate that vibration trouble is confined to steel-cored aluminium lines where the area of the steel core is less than 40 per cent of that of the total conductor. There are three known methods of dealing with vibration at joints and points of suspension, viz. (i) that used with great success by the Electricity Commission of Victoria, Australia, on 132-kV lines; (ii) that used by the Hydro-Electric Power Commission of Ontario on their 220-kV lines; and (iii) the Varney method, patented by the Aluminium Corporation of America. The grid system is being carried out by British engineers with British or British Empire materials wherever these are available, and it is gratifying to note that, within the British Empire, there are at least two methods in use for dealing with vibration trouble if the need should arise. The successful operation of the grid will depend largely on the satisfactory operation of the transformers and, from this point of view, I inquired closely into the performance of large units when last in the United States. I was impressed by the regular weekly examination of the electric strength of the oil in the transformers, and the reconditioning of the oil if its strength fell below the prescribed standard; also by the large number of really high-voltage transformers that were insulated with paper. The British grid substations are being equipped with plant for the reconditioning of the transformer oil, but can the authors say whether the high-voltage transformers are also being insulated with paper? The authors quote the cost per mile of lines based on the Central Scotland contract. Since the paper was written further contracts for England have been let, and perhaps the authors would now give corresponding figures for the various areas concerned. The British practice is to use anti-climbing devices in order to prevent unauthorized persons from climbing the towers. A good deal of expense in first cost and subsequent maintenance is involved and it is doubtful whether, on 132-kV lines, the expense is warranted because, even if a mischievous boy climbed the pole and got right out to the end of a cross-arm, he still could not touch the live conductors without deliberately climbing down to the string of suspension insulators.

---

* Paper by Messrs. JOHNSTONE WRIGHT and C. W. MARSHALL (see vol. 67, p. 685).

Mr. P. J. Robinson: The authors refer to the protective value of aluminium stranding against corrosion of the steel. Their statements would be perfectly correct provided that there have been no kinks or openings of the strand during erection, but it would appear that once a strand has been opened, and the steel is accessible to the weather, both corrosion and electrolytic action can take place in an acid or alkaline atmosphere. Has any attempt been made to coat the steel wire with bitumen previous to applying the aluminium conductors, and have any experiments been made of extruding a tube of aluminium over the steel core? I believe that this would be quite possible, and would certainly eliminate the defects I have mentioned. On page 695 (vol. 67) the authors mention arcing rings and horns on insulators; I am not clear whether they refer to bushings on circuit breakers and transformers, and they state that the use of arcing rings, etc., is by no means a standard practice. Has this view been modified since the paper was written, owing to the introduction of the one-piece stone insulator bushings which are being used so extensively on the Continent, where apparently they do not think it necessary to use arcing rings and bushings. I agree with the authors that all the propaganda that is being used against the erection of overhead lines is quite unjustified. When compared with the enormous mass of telegraph and telephone wires erected along main roads, the appearance of the overhead lines in connection with the grid becomes quite pleasing. In cases where it is necessary to put the lines underground in order not to interfere with the amenities of the district, is it proposed to step down the voltage for transmission by cable and to step up again on reverting to the overhead line, or is it proposed to operate cables at 132 000 volts? In either case, do the authors anticipate any trouble due to surges where lengths of cable connect sections of overhead lines? Fig. 8 shows a section of the line which is at present joined by isolating switches only and which has apparently been included as an emergency link. The two isolating switches are in series and are in very close proximity to each other, and I presume that the two switches have been put in with a view to enable the operator to work on one switch without one side being alive. At first glance this seems to be rather an expensive matter, and it is questionable whether it is warranted under the circumstances. A further disadvantage in this link, considering the interlocks referred to on page 703 (vol. 67), would appear to be that in the event of the emergency link having to be closed, assuming that the link controlled by the oil circuit-breaker is out of commission, the supply to both banks of transformers would have to be cut off; i.e. if both banks of transformers were on load, the circuit breaker on the healthy transformer would have to be opened until such time as the link had been closed, and the circuit breaker would then have to be closed again. In the meantime the supply would have to be discontinued. Do the authors rely on the galvanizing of the towers for preservation, or are the latter to be painted also? In many cases abroad they are painted, but I understand that this is rather a question of first cost, and that the operating engineers on the Continent would prefer to have the towers galvanized, as they find that painting is both expensive and difficult. Regarding oil circuit-breakers, have any tests been carried out on these to ensure that they have a rupturing capacity of 1 500 000 kVA? This is an extremely interesting point, as I understand that we have no testing plant in this country capable of testing up to such high rating, which seems to be rather discreditable in view of our large share in the construction of circuit breakers for the Dominions and elsewhere. The authors call for multiple-break oil circuit-breakers. I am rather under the impression that double break means the evolution of a double quantity of gas when the arc is undergoing rupture. Under these circumstances, is the multiple break warranted? Have the authors any views as regards the operation of these breakers, as to whether they should be operated by solenoid or centrifugal gear? Is it the intention of the Board to have an operator in these substations throughout the 24 hours? On page 710 (vol. 67) it is stated that there is a tripping circuit which operates the circuit breakers if the oil in the transformers rises to a certain predetermined temperature. Is any indication given in the control room as to why this circuit breaker has operated, i.e. whether it has opened under fault conditions or owing to high temperature? In Table 3 the weight of the transformers seems to diminish, in certain cases, with an increase of output. Is this an error? On the Continent it is a standard practice to erect towers in one piece, and haul them up by means of an anchor pole, using a caterpillar tractor for hauling purposes. I should imagine that mounting these towers on site would lead to rusty bolts and damaged galvanizing. No attempt seems to have been made to guard telephone or other wires which pass under the high-voltage lines. Is it the intention of the Board to ignore this matter entirely? Have the authors any information as to the trouble caused by salt-laden winds, which occasionally cover the insulators with a heavy coating of salt?

Mr. W. Fennell: I must confirm the remark which I made in the discussion at Manchester, namely that the cost per mile of the grid, particularly on the single-circuit line, is reasonable. A cost of £1 500 per mile for a single-circuit line of this description is, I think, a remarkable achievement. Of course, the negative profit of the contractors must be taken into account, but the result is extremely good. The paper does not state the method used when entering and leaving towns and cities. I should like to know how the 132-kV circuits of the grid will be led to the Clarence Dock at Liverpool. Warrington is to be a central switching point, and I imagine that the method of leading high-voltage lines in and out of the power-station yard will be a matter calling for a great deal of care on the part of the designers. The controversy over the Battersea power station turns upon the point of leading e.h.t. mains into and out of London. On one section of the secondary grid, not many miles from here, the line passes over the roofs of some suburban villas. It is inevitable that the lines shall pass above buildings, and I think further particulars in this connection would be useful. I think that the Board should make some tests in connection with the subject of local corrosion of line conductors. The question of aluminium and its power of resisting atmospheric impurities is very complicated. In South Staffordshire, with an acid atmosphere somewhat similar to that of Pittsburg, my experience indicates that only aluminium should be used. While brass lampholders failed in a year or two, aluminium holders seemed to last indefinitely. I erected a copper line in 1911 and it corroded at a rapid rate. An aluminium line which followed it was in good condition when I inquired two or three years ago. On the other hand, aluminium will not withstand an alkaline atmosphere. I am interested particularly in the secondary lines of the grid from the point of view of distribution, apart from the supply of power at existing power-station sites. The supply of rural areas does not seem to have been considered in great detail up to the present. Parts of the Western coast of England experienced a very bad brine-storm in November 1927, and high-voltage lines were affected for several hours. Steps should be taken to ensure that a sufficient factor of safety for insulators is provided in these areas. I do not say that the standard insulation will fail, but I think it would be better if it were reinforced. With regard to propaganda in relation to the preservation of rural England, I suggest that those who are concerned with obtaining wayleaves should not allow themselves to be induced to put lines underground simply to meet the views of local landowners regarding the appearance of overhead lines. Every such case is used to enforce further concessions.

Mr. E. M. Hollingsworth: I recently inspected some of the work carried out in connection with the Scottish Central section of the scheme, and was surprised at the speed at which the towers could be erected. I agree that these are pleasing in appearance and interfere very little with the landscape. A previous speaker mentioned the apparent difficulties of leading out the overhead lines from power stations in congested districts, but I question if there could be any more difficult example than that at Dalmarnock, where the overhead lines are already erected. On the question of corrosion of conductors and of the properties of insulators, I would point out that nearly three years ago, at the request of the Electrical Research Association, insulators of many kinds were exposed, in the Widnes district, to various chemical atmospheres, and also near the riverside in order to ascertain the effect of salt air. All the specimens are examined periodically, about once a month, and the condition of their surfaces as regards the formation of deposit, and the nature of the deposit, are recorded. We are assured by the Association that this co-operation is helpful in the investigation which they are carrying out in connection with the surface properties of insulators. I would mention that we are also co-operating in investigations as to the property of metals most suitable for use as overhead conductors, and for some time we have had placed in our works specimens of conductors of various kinds, some of these merely being exposed to the atmosphere, and others being, in addition, connected in circuit at various voltages.

Mr. F. V. L. Mathias: I was recently approached by a consumer of ours in Warrington, over whose works the Board propose to run overhead lines. These works generate a considerable number of gases: sulphurous acid, salicylic acid, ammonia and nitrous oxide. He asked my opinion as to how the conductors would be affected by these gases, as he did not want the risk of the lines falling on to his works. I must say that, in dealing with overhead gear on the tramways, it is our experience that galvanized steel is not particularly good; the wires have to be constantly renewed and constantly inspected. The inspection of a steel core enclosed in aluminium strands would be a rather difficult matter. It might be preferable to have the steel outside, so as to facilitate inspection, since it is practically impossible to detect any corrosion which may be taking place on the inside steel core. Even quite small areas of localized corrosion in the steel core would seriously affect the strength of the line.

Mr. H. Midgley: Can the authors give any details of the method to be adopted for protecting the transmission towers from corrosion? Painting is expensive and would entail a large and continuous labour charge. In addition the lines would have to be put out of commission during the painting process. Galvanizing, if adopted, is likely to suffer damage during erection, and the rapidity with which local corrosion, consequent upon such damage, becomes general is too well known to require further comment. The possibility of the metal spraying of completed towers appears to have much in its favour, as with such a method not only the tower members but also the nuts and bolts would receive a thorough protective coating. One aspect of the actual operation of the grid which appears to be fraught with considerable difficulty is that of paralleling two areas when, owing to a fault or some other cause, the interconnecting switches have tripped out and the two systems have become separated. Suppose, say, Liverpool and Manchester are normally running in synchronism, and that an exchange of load is being effected in one direction along the interconnecting line. If a separation occurs there will be a tendency for the frequency of the overloaded undertaking to fall slightly. The difficulty of re-establishing equal frequencies on two such large systems is obvious. Admittedly, this is probably the worst possible condition, but even if the frequencies of the two separated undertakings are identical the synchronizing current necessary to pull two complete areas into step might conceivably be quite sufficient repeatedly to trip the switches. An engineer who was associated with one of the interconnecting stations in this country some years ago had two sections of the system under his control, absolutely separated. They were both running, but not in phase, and owing to the very small breaking capacity of the switches the two halves could not be synchronized for about two hours, due to the tripping of the switches by the synchronizing-torque current. Admittedly, owing to the greatly increased breaking capacity of the switches being installed on the grid network, the possibility of such a situation arising is very remote, but at the same time it must be borne in mind that the size and number of the units interconnected by these switches have also greatly increased. I shall be glad to hear to what extent this aspect of the interconnection of large undertakings has been investigated.

Mr. H. R. S. Preston : It is stated that the general design of the lines complies with the Regulations of the Electricity Commissioners, but in and around Glasgow the lines are erected over railways, tramway equipment, telegraph wires and houses, without any special guarding arrangements and, although the factors of safety based on the specified loading conditions may be considered conservative, I think that some special means should be adopted to prevent damage in the event of a conductor breaking or falling, especially as it is recognized that trouble due to vibration may occur. Such an accident might cause much injury both to life and property, and might cause considerable public opposition to the scheme. It is stated on page 697 (vol. 67) that "The arcing horns and rings give a definite path for transient discharges and protect the insulators and conductors from power arcs." It is very necessary to protect the conductors from power arcs which might be caused by lightning and abrupt load-changes. In order that arcing should take place between the arcing horn and ring, the minimum distance specified between live metal and tower steelwork should not be less than the maximum distance between the arcing horn and ring of any insulator string. The specified minimum distance between live metal and tower is stated to be 42 in., whereas the distance between the ring and horn on the tension set is over 45 in. and, therefore, arc-overs are likely to occur between live metal and the towers. Is it the opinion of the authors that the arcing distance on the tension sets should be reduced to 42 in. or less? If so, then the only reason for increasing the number of discs in any insulator string should be bad atmospheric conditions, because whatever number of discs is added the distance between horn and ring should not be greater than that between live metal and tower.

Mr. L. Breach : The authors state that, owing to the change-over in frequency at Glasgow, it was found necessary to operate one circuit at 25 cycles per sec. and another circuit on the same tower at 50 cycles per sec. and, apparently, at a different voltage. I should like to ask, purely by way of interest, as I understand that this is only a temporary expedient, whether during the change-over any difficulty has been experienced owing to electrical swing due to the different frequencies and voltages at which the lines are operating. If so, what is the extent of this swing, and has it any definite period?

Dr. T. H. Turney : I am specially interested in the formulæ given for telephone interference, and although I have not seen how they are derived, it is interesting to note that Heaviside gives kindred formulæ for cylindrical waves of flux when electrostatic capacity is ignored. The authors mention that the formulæ become inaccurate at higher frequencies. Is this due to the omission of capacity effects? In other words, do the formulæ assume waves of diffusion, and not true electromagnetic waves? Some time ago two of our engineers were installing some telephone apparatus on a power system and, when they were making some connections on the telephone system, they noticed a series of sparks running along the tags of the telephone cable, owing to induction from a surge on the power system. It therefore appears that this question of interference due to surges has some importance. Can the authors give any information as to the way in which they propose to measure surges?

Messrs. Johnstone Wright and **C. W. Marshall** (*in reply*): Replying to Mr. Welbourn, delays in obtaining wayleaves have proved a serious obstacle to the construction of the "grid." The Central Electricity Board has, however, respected the rights of landowners and occupiers and has made appeals to the Ministry of Transport only in cases where all other methods of approach have failed. As for corrosion, the cases quoted by Mr. Welbourn regarding the behaviour of aluminium in industrial areas of France and the United States provide additional evidence of the soundness of the decision to use aluminium-steel conductors. The circumstance that vibration troubles have occurred only where the area of the steel core is less than 40 per cent of that of the whole conductor has already been noted. The "grid" conductors are not within the danger zone as defined in the above way, but the ratio of areas does not seem to be a very satisfactory criterion of safety from vibration; for example, one would hardly expect the addition of another layer of aluminium to make a conductor worse. Theoretical investigations are at present being made which will place the subject of vibration on a sounder basis. Some degree of vibration has been noted at isolated points on the "grid" lines, but no cases of a dangerous nature have yet been reported. The methods of overcoming vibration trouble mentioned by Mr. Welbourn have been supplemented by a new scheme, devised by engineers of the Electrical Research Association, which appears to have definite advantages. As regards transformers, it is obvious that oil maintenance is a matter of great importance, and it may be that the weekly oil inspection and testing are justified. Permanent oil-filtration plant is provided at all 132-kV "grid" substations, so that very frequent oil treatment may be resorted to at low cost. Paper is largely used as an insulating material in the "grid" transformers. The contract prices for lines in other areas have been somewhat lower than those for Scotland. The provision of anti-climbing devices is dictated by legal and political requirements, and there is at present little hope of it becoming possible to omit them in Britain, although in other countries only the oldest lines have any anti-climbing devices on their towers.

Turning to Mr. Robinson's remarks, the danger of corrosion being started by wires becoming kinked during erection is not negligible, but the line conductors, where there are two layers of aluminium, are not likely to give trouble. The earth wire has only one layer of aluminium. The steel core is bitumenized (in the manner mentioned by Mr. Robinson) before the aluminium is laid over it. Conductors in which an aluminium coating is extended over steel have not been considered for the "grid" up to the present. The scheme has, however, possibilities, and if wires of this type become available their properties and cases will be investigated as an alternative to the present construction. It does not by any means follow that the extruding system would be better than ordinary stranding; as the different coefficients of expansion are elastic, the electric and magnetic properties of aluminium and steel make it difficult to be sure that no trouble would occur when these metals are closely allied in the form of a tube and core. Arcing horns or rings are used on circuit-breaker and transformer bushings. The stoneware bushings referred to by Mr. Robinson are, so far as we are aware, used only in Germany. They make a useful alternative to porcelain or steatite and are said to be much cheaper. In some cases they are used without arcing horns, but this omission is by no means universal. From an æsthetic point of view, it is generally agreed that the "grid" lines compare favourably with telegraph and telephone lines. Only in a few cases has it been necessary to depart from the use of overhead lines for 132-kV working. In these cases 132-kV cable is being used. Joining up lengths of cable with overhead lines introduces an electrical discontinuity, which changes the form of any impulse passing along the lines. Experience on lower-voltage systems has proved that the cables are of value in protecting inductive apparatus from potential surges, and it is expected that similar results will be obtained on the 132-kV system. The two isolating switches shown in Fig. 8 are necessary to enable maintenance work to be carried out safely. The standard method of protection for the tower material is galvanizing. Painting will be adopted in one scheme where special steel towers are being used. Our own experience of Continental practice indicates that the maintenance engineers prefer galvanizing, although this method of protection is rarely used in France and Germany. No tests of the rupturing capacity of 132-kV circuit breakers have been made in Great Britain. Reliance has been placed on tests made on lower-voltage switches, and on information obtained from America, to ensure that the rupturing capacity will reach the required standard. Circuit-breaker failures have as a rule occurred on comparatively low-voltage systems. While it is possible that this is merely a result of the law of averages, combined with the fact that many switches which have failed were of poor design and construction, the thermal and mechanical stresses which arise from very large currents are undoubtedly less severe on very high-voltage breakers. The creation of a British testing plant, where such matters could be settled, is very desirable. There has been no attempt to standardize the type of circuit breaker to be used on the "grid," and both 2-break explosion-pot and multiple-break types will be used. Solenoid operation is usual: its chief disadvantage is the large power required for closing purposes. No centrifugally-operated breakers have yet been ordered. It is not anticipated that special operators will be required throughout the 24 hours at all "grid" substations. Tripping of circuit breakers caused by protective relays is definitely indicated on the relays involved. Maximum pointers are provided on temperature indicators. Table 3 in the paper as printed in the *Journal* contains the weights of transformers as given in the contracts between the Board and the manufacturers. The method of tower erection used extensively on the Continent, whereby the complete tower is pulled up into position by a winch or tractor, is generally applied to narrow-base riveted towers. The bolted wide-base towers used on the "grid" are erected vertically. Careful inspections are made to ensure that the galvanizing is kept as nearly intact as possible. The subject of guarding of lines at crossings has been closely studied. The Regulations of the Electricity Commissioners and the requirements of the Post Office are fully complied with, although in some instances the form of protection afforded differs from that usually adopted. The engineers of the Board have made a careful investigation of the effects of salt-laden winds. The lines have been kept as far inland as possible. Special insulators are being tried with a view to overcoming the troubles due to conducting deposits,.

Mr. Fennell refers to the difficulties of bringing 132-kV lines into cities. These difficulties are considerable, and the costs of the lines are greatly increased thereby. Special constructions are being considered whereby lines can be brought in over and along canals or railways. Double transformation and the use of lower-voltage cables will only be resorted to where the above methods cannot be applied. If it had been absolutely forbidden to take high-voltage lines over buildings, the cost of the "grid" would have been increased to a very serious extent. Great care is taken with the construction in order to eliminate the possibility of trouble occurring, and special samples of aluminium and galvanized steel wires and fittings are mounted in the worst districts so as to give the maintenance engineers convenient and timely warning of any corrosion which may occur. The evidence regarding relative rates of corrosion on brass, copper and aluminium in Mr. Fennell's district is interesting. Consideration of the subject of supplies to rural areas does not come within the scope of the paper and has not been mentioned. The matter has, however, not been neglected by the Board. With reference to brine storms, the determination of the amount which can justifiably be spent to ensure trouble-free operation in all line sections is very difficult. The insulation provided on the lines is adequate for the great majority of the sections in all ordinary conditions met with in Britain. It is expected that certain lines will have to be specially insulated. Provision has been made on the towers so that anti-fog insulators can be fitted where required. In no circumstances are lines being cabled merely to meet the views of local landowners regarding the appearance of overhead lines. On the other hand, the best available advice has been taken to ensure that lines will not be unsightly.

We are pleased to note that Mr. Hollingsworth has remarked on the speed of erection of the towers. We hope and believe that the British contractors will show themselves to be capable of attaining the highest standard in this respect. So far as we are aware, no more difficult work in overhead line construction than the Glasgow section of the "grid" exists in the world. The Widnes experience regarding the effects of chemical- and salt-laden atmosphere should be of great value, and details of the results obtained are awaited with interest.

In reply to Mr. Mathias, the effects of sulphurous acid, salicylic acid, ammonia and nitrous oxide on overhead lines are obviously dependent on the degree of concentration of these chemicals in the atmosphere. Presumably, the degree of concentration does not exceed that usual in the neighbourhood of modern chemical factories. In that case, the effects can be overcome by painting of towers and conductors and washing of insulators. The proposal that the rôle of steel and aluminium should be reversed does not commend itself to us. Ease of inspection of the steel is, in our opinion, more than counterbalanced by the higher rate of corrosion of steel relative to aluminium and the greater impedance and eddy-current losses. Experience has also shown that the degree of protection afforded by aluminium is very high, and that there is little fear from internal corrosion.

Mr. Midgley mentions metal spraying as a method of preventing corrosion. This suggestion opens up great possibilities, but, so far as we are aware, the method has not been developed to such an extent as to make it possible to use it on the "grid" towers. In the circumstances foreseen by Mr. Midgley, where two large sections of the "grid" which normally operate in parallel become disconnected, re-paralleling will generally be done on the lower-voltage switches joining the grid transformers to undertakings. Provision, in the form of condenser tappings on the circuit-breaker bushings, is also being made whereby sections can be paralleled on the 132-kV side. The particular instance mentioned by Mr. Midgley would be made much more useful if he would state definitely the capacities of the two interconnected systems and of the interconnecting link.

We note from his reference to crossings that Mr. Preston is of the opinion that some special means should be adopted to prevent damage in the event of a conductor breaking or falling. All precautions which are economically possible have been taken to this end. Mr. Preston should note that the minimum distance between live metal and towers occurs only when a conductor is in its position of maximum displacement from normal. The probability of an arc-over taking place between live metal and towers, relatively to the arc taking its normal path between arcing points, is very small. The arcing distance on tension sets has deliberately been set above that on suspension sets in order to prevent still further the possibility of damage to highly-stressed tension insulators. Increasing the numbers of discs per string, in addition to adding to the insulating value of the strings, also definitely reduces the electro-mechanical stresses on the individual units.

Replying to Mr. Breach, no untoward experience has so far been encountered on the lines in Glasgow where two circuits working at different frequencies are carried on the same towers. The open-circuit induced voltages on neighbouring lines are fairly high, but the energy transfer is small, and for this reason the temporary use of the lines in the manner described is considered to be sound practice. If Mr. Breach will state more precisely the nature of his difficulty we shall be glad to investigate the subject more closely.

The formulæ given for inductive interference are briefly dealt with in the "Directives" of the Comité Consultatif International, and definite references to the original work of Rudenberg are provided which will enable Dr. Turney to correlate the formulæ quoted with those of Heaviside. The reason for the discrepancy between values deduced from formulæ and those determined by experiment has not yet been elucidated. The experience quoted by Dr. Turney, in which sparks running along tags of telephone cable were observed, is of interest. We should be glad to have information regarding relative displacements of the power lines and communication lines figuring in this experience. It is frequently considered that the erection of the "grid" lines will add appreciably to the damage arising from induced voltages, but it should be remembered that, although the short-circuit currents on the "grid" lines will be larger than on existing power lines, in many instances communication lines are erected on the same towers as power lines and with a very small separation. In such cases communication work can be conducted without serious trouble due to inductive effects. It is therefore anticipated that the comparatively large displacements which exist between the "grid" lines and the communication lines will effectively prevent the occurrence of serious trouble.

NOTES ON THE 3-SWITCH TYPE OF SUBSTATION.

The following notes are based on Fig. 6 (vol. 67, p. 699):—

In normal operation the cross-over connection is open. When one transformer only is in use it is closed.

In the case of a line failure, the fault current is broken on the line switch and the corresponding transformer switch in parallel. One transformer is thus temporarily disconnected, but can be re-connected after opening the line isolator.

A faulty transformer is cut out of circuit on both high- and low-tension sides.

All possible faults on any part of the substation gear are cleared by one or other of the above cases.

A section switch can be taken out of service for overhaul, and a supply taken through both transformers with the cross-over connection in use, in emergencies. When both transformers are in use it is possible to reclose after a line has been disconnected by means of the transformer circuit breaker, thus having the reactance of both transformers in circuit.

When the station is to be used for working with one transformer only, the three circuit breakers are kept in use and the cross-over connection is closed. The transformer which is out of use is disconnected by means of its isolator switch and low-tension circuit breaker.

In the case of line failures, the section circuit breaker, and the transformer circuit breaker adjacent to it, operate, leaving the transformer connected to the sound line through the remaining circuit breaker.

In the case of a transformer failure, both 132-kV transformer circuit breakers and the transformer lower-voltage circuit breaker open.

INSTITUTION NOTES.

Honorary Member.

At the Ordinary Meeting of the Institution on the 9th January the President announced that the Council had that day elected Sir Richard Glazebrook, K.C.B., D.Sc., F.R.S., an Honorary Member of the Institution.

Local Hon. Secretary for Italy.

Mr. L. Emanueli has been appointed by the Council as the Local Hon. Secretary of the Institution for Italy, to fill the vacancy caused by the death of Mr. Semenza.

Subscriptions of Retired Members.

The Council have amended the Rule (see *Journal*, 1927, vol. 65, p. 93) in regard to the subscriptions of Corporate Members of long standing who have retired from the profession. The revised Rule now reads as follows:—

> "Any Corporate Member who has reached the age of 60 and has retired from the practice of his profession or business, may apply to the Council to remit his future annual subscriptions, provided that his membership of the Institution has been continuous for at least 25 years. If he desires to have the publications of the Institution he will receive them on payment of £1 1s. 0d. per annum."

Graduateship Examination Results: November, 1929.

*Passed.**

Baldwin, C. S. S. (Manchester).

Viant, J. R. (Southampton).

Further results, relating to candidates who sat for the Examination abroad, will be published later.

Proceedings of the International Conference on Large Electric High-Tension Systems.

The Secretary has been requested to call the special attention of the members to the subscription form enclosed with this issue of the *Journal*, for copies of an English translation of the Proceedings of the Fifth Session of the above Conference held in 1929. The Proceedings will contain the 100 papers presented at the Session and full reports of the discussions, and, in order to justify the cost of publishing an English translation, at least 300 subscriptions will be necessary.

Of the papers presented, 30 deal with the design and manufacture of generating and transforming plant,

---

* This list also includes candidates who are exempt from, or who have previously passed, a part of the Examination and have now passed in the remaining subjects.

38 with overhead lines and cables, and 32 with parallel operation, earthing the neutral, protection against surges, metering h.t. energy, etc. They contain recent information in regard to developments since the last meeting of the Conference and were written by experts from 15 different countries. Members wishing to subscribe should fill in the form and return it with a remittance of the appropriate amount to the Secretary, The International Conference on Large Electric High-Tension Systems, Boulevard Malesherbes 25, Paris.

American Society of Mechanical Engineers.

The American Society of Mechanical Engineers will celebrate its Fiftieth Anniversary in April 1930, at Washington. The principal event will be a convocation in that city, starting on April 7th, but this will be preceded by a reception to the delegates at the home of the Society in New York on April 5th, and a pageant depicting the first meeting of the Society. Members of The Institution of Electrical Engineers who may be in the United States at the time are cordially invited to participate in the meetings. Full particulars can be obtained from the Secretary of the American Society of Mechanical Engineers.

The Benevolent Fund.

The Committee of Management desire to draw the attention of the members to the appeal for funds which will be found on the last page of the cover of this issue of the *Journal.*

Membership Transfers.

The following transfers have been effected by the Council in accordance with the provisions of Bye-Laws 14, 15 and 18:—

From Companion to Associate.

Ryan, William Albert, B.A., B.L.

From Associate to Companion.

Adlard, Howard T.
Alabaster, Geoffrey Hubert.
Alabaster, H.
Anderson, Frederick William M.
Atherton, Arthur.
Atkinson, George Alexander S.
Barker, Arthur Henry, B.A., B.Sc.
Barr, Thomas Hall.
Barrett, Harry George.
Beatty, Andrew Henry.
Bigge, Denys Leighton S.
Bishop, Walter Frederick.
Blackwood, John A.
Blundell, J. Wagstaff.
Booth, Lancelot Henry, M.A., LL.M.
Boyd, William Robert E.
Brooks, Emile.
Burbury, Henry Herbert T.
Burnham, Walter Witt.
Byng, Ernest Gustav.
Cameron, Sir Maurice Alexander, Major, K.C.M.G., late R.E.
Challoner, William.
Clough, William Thomas.
Cohen, Jacob Whaley, Lieut.-Col., C.M.G., C.B.E., D.S.O., T.D.
De Roemer, Charles William.
Ditmas, Francis I. L., Lieut.-Col., D.S.O., M.C.
Dunlop, Daniel Nicol.
Eastick, John Clare N.
Evans, Bertram Charles.
Falmouth, The Rt. Hon. the Viscount.
Faning, Vyvyan Eaton.
Faraker, Frederick Cecil.
Ferguson, Harry Edmund.
Fleming, Albert Arnold.

From Associate to Companion—continued.

VOLTAGE CONTROL OF LARGE ALTERNATORS.

By H. W. TAYLOR, Member.

(*Paper first received* 10*th October*, 1928, *and in final form* 8*th November*, 1929; *read before* THE INSTITUTION 28*th November*, *and before the* SOUTH MIDLAND CENTRE 12*th November*, 1929; *also before the* NORTH-EASTERN CENTRE 13*th January*, *and before the* NORTH-WESTERN CENTRE 18*th February*, 1930.)

SUMMARY.

The voltage control of large alternators is considered, with special reference to large high-speed machines now being installed in capital stations.

With a view to stimulating discussion the treatment is descriptive and is dealt with under the following headings:—

Exciter stability.
Exciter response.
Alternator stability.
Alternator response.
Combined response of alternator and exciter.

INTRODUCTION.

The problem of maintaining constant voltage on a generator when large loads are frequently thrown on and off is still met with in some mills and factories which, for good reasons, still generate their own power.

With power supply from capital stations, and with increasing size of systems, incidental variations in legitimate load have become relatively small and only system faults constitute changes of load which require adjustment of the machine excitation.

As systems expand they are sectionalized, with interconnecting reactors between sections. When a severe fault occurs close to the generating machinery in one section, it is unlikely that any practical design or mode of operation can maintain full voltage. Indeed, there is a difference of opinion among operating engineers as to whether the excitation of the machines should be allowed to increase appreciably under these conditions. When, however, a fault occurs at a distant point or in an adjacent section, it is usually desired that the excitation on the generators be increased quickly to the limit of the exciter capacity, so as to maintain the supply voltage as near to normal as possible, at any rate on those sections of the system which are not local to the fault.

Side by side with increase in size of system, there is also a tendency to increased sizes of generating units. The magnet systems of these machines require larger stores of electromagnetic energy, which tends to a longer time in responding to changes in the excitation circuits intended to maintain normal voltage after sudden load-changes.

The study of the machine voltage control requires consideration of "stability" and "speed of response," both separately and in combination. Stability determines whether the drop or rise in voltage becomes cumulative after certain load-changes, and response determines the quickness with which, by a change in the excitation circuits, voltage can be restored when temporarily disturbed by load-changes. In some cases when a change of load tends towards instability a quick response can restore stability before the machine voltage has become unduly depressed.

Voltage control is nowadays required to be automatic within a few per cent of normal value. As direct manipulation of the alternator field circuit is not practicable, the control of the generator voltage is effected by changes in the exciter field circuit, so that it is necessary to consider the stability and response of the alternator and its exciter in combination. However, the consideration of the subject is simplified by discussing, firstly, the exciter alone, secondly, the generator alone, and finally the two in combination as a generating unit.

EXCITER STABILITY.

Two kinds of instability of the exciter may occur; these may be designated "load instability" and "inherent instability."

Exciter Load Instability.—This is caused by the load current in the armature overpowering the field excitation. Assuming that no alternator field rheostat is used, so that the exciter is loaded simply upon the alternator field windings, the exciter load current and voltage will increase or decrease together except in so far as a higher load causes an increase in resistance due to the temperature of the alternator field coils. This increase may be more than 33 per cent above the cold resistance when the unit is put into service. This feature, together with the saturation which occurs, helps to make the exciter stable at heavy loads, but some attention to design details is necessary to guard against exciter instability at light loads. It is suggested that the air-gap should be such that at low exciter voltages the field ampere-turns are greater than the corresponding armature reaction with the alternator field cold. In addition to this precaution, equalizing connections should be provided on the armatures where lap windings are used.

A further aspect of exciter load instability which requires consideration is that, when load is thrown on to the alternator, its excitation tends by virtue of the inertia of its magnet system to assume, temporarily, the new and larger value of excitation required for maintaining constant voltage under the new load conditions. Thus the armature may be loaded before its field circuit is adjusted and its field current brought up permanently for the new condition. This effect will usually be taken care of by the proportions of design just proposed; but when the load change is abnormal, and automatic means of causing the exciter field circuit to respond quickly are not in use, a shunt exciter may lose its voltage altogether and then build up with reversed polarity. In the meantime the supply is subjected to a surge as the alternator slips a pole and re-synchronizes with other generators on the system whose exciters have not been so affected. Separate excitation of the exciter field is a preventive against complete reversal.

It has been suggested that a certain amount of series winding on the main poles is helpful in regard to the load instability of a shunt machine, but when the series ampere-turns are suddenly increased the shunt ampere-turns decrease correspondingly because of the inertia of the exciter magnet system, so that the net excitation is not immediately affected. Inasmuch as load instability arises from the cross-magnetizing action of the armature current, a pole-face, or, as it is usually called, a compensating winding, affords a cure, and a damping winding, consisting of a set of short-circuited bars, affords a partial remedy.

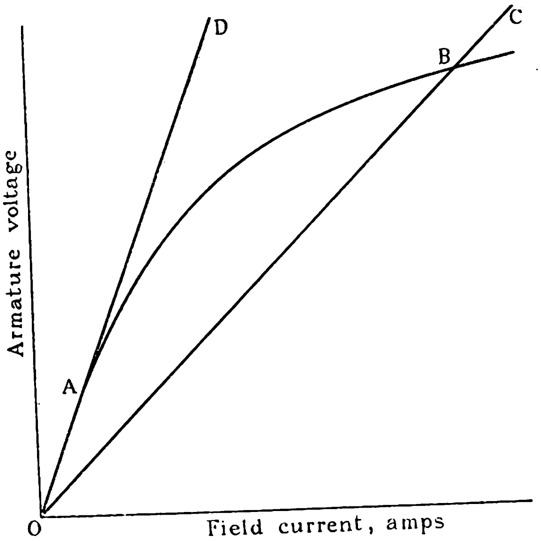

Fig. 1.

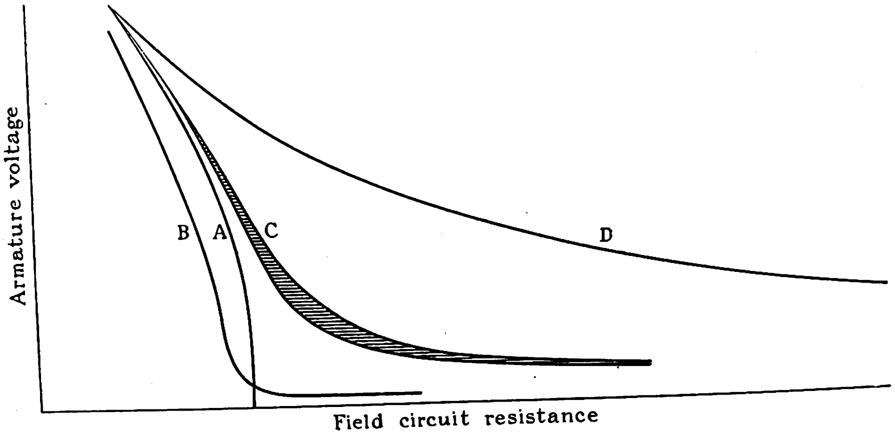

Fig. 2.—Curves illustrating grading of rheostats for different types of exciters.

Inherent Instability of Exciters.—In order that a shunt exciter may be stable at a given voltage, it is necessary that a straight line drawn through the origin of the saturation curve should cut the curve at this point. For instance, if OAB in Fig. 1 represents a load saturation curve connecting field current and armature voltage, then as a straight line drawn through the origin definitely cuts the saturation curve at B, the voltage is inherently stable at this point.

The slope of the straight line OB gives the resistance in the exciter field circuit for this voltage. As further resistance is introduced into the exciter field circuit, the line representing it becomes steeper and ultimately a certain value of resistance, represented by, say, OD, corresponds to the initial shape of the saturation curve, which, unless some precaution is taken, may be very nearly a straight line through the origin up to an appreciable proportion of the maximum exciter voltage. With resistance corresponding to OD, the exciter voltage will settle down to a value corresponding to A, but if the resistance be further increased the exciter voltage will disappear, the exciter having become inherently unstable. However, shunt exciters are not so inherently unstable as indicated by the saturation curve in Fig. 1, because they must have a small remanent magnetism in order to build up, and the saturation curve therefore does not pass exactly through the origin.

The instability of the shunt machine presents itself to the designer as a difficulty in suitably grading the shunt rheostat in order to obtain uniform increments in voltage. For this purpose it is convenient to exhibit exciter stability by a curve connecting field circuit resistance and armature voltage, and a curve corresponding to the saturation curve shown in Fig. 1 is shown as curve A in Fig. 2. The difficulty in grading a rheostat for equal increments of exciter voltage will be obvious.

Various attempts have been made to stabilize the shunt machine at lower voltages. Some of these consist in introducing premature saturation in some short length of the magnetic circuit, while others attempt to provide an initial voltage which is independent of the shunt field circuit.

Two means of effecting the first method are shown in Figs. 3(*a*) and 3(*b*). The former shows the pole cut so that for a short length it becomes prematurely saturated, while the latter shows a shim used between the pole core and the frame. The shim is perforated with holes and so produces local saturation as flux passes from the pole core and into the frame. The use of a cast-iron magnet frame in preference to one of steel helps the stability of a shunt machine, but any method of producing initial saturation must of necessity limit the maximum voltage. A curve for studying rheostat grading corresponding to a small amount of initial saturation is shown as B in Fig. 2. This shows easier conditions as regards rheostat grading than curve A, but some difficulty still remains owing to the field-coil resistance varying with temperature. A different setting of the field rheostat is therefore possible for the same load, according to whether the loads previously carried were high or low. This necessitates a fine grading over a relatively large portion of the rheostat.

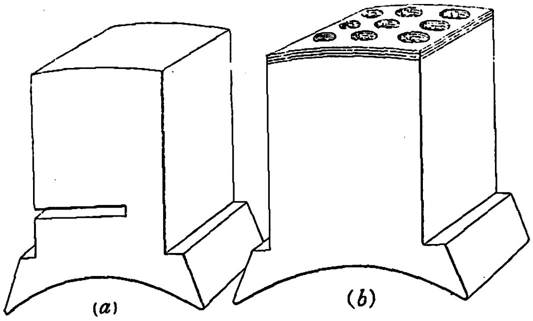

Fig. 3.

Methods of providing a small initial voltage consist of making either a part or the whole of the magnetic pole cores of some hard magnetic material or, alternatively, of providing a small coil in addition to the shunt winding, which can receive a trickle current from a battery. Curves corresponding to these methods are shown as C in Fig. 2, but the use of hard magnetic material is attended with some disadvantage in that the rising magnetization curve of such material differs from the falling one, especially at low flux densities. The possibility of a rise or a fall in voltage at any time in this region of curve C in Fig. 2 is shown by shading.

The use of a small amount of initial excitation is a step towards completely separate excitation. This ensures inherent stability. A curve corresponding to this condition of excitation is shown as D in Fig. 2. In many stations, however, a continuous source of supply for the full excitation of the exciter is not available, for even when a battery is installed many engineers are reluctant to allow the operation of the unit to depend ultimately upon it. In order to make separate excitation of the exciter acceptable the practice has been initiated of building, as an integral part of the machine, a small service exciter which operates at constant voltage with a saturated magnetic circuit and which, therefore, is perfectly stable for exciting the main exciter. A neat arrangement consists of combining the service exciter in the same frame as the main exciter, as shown in Fig. 4.

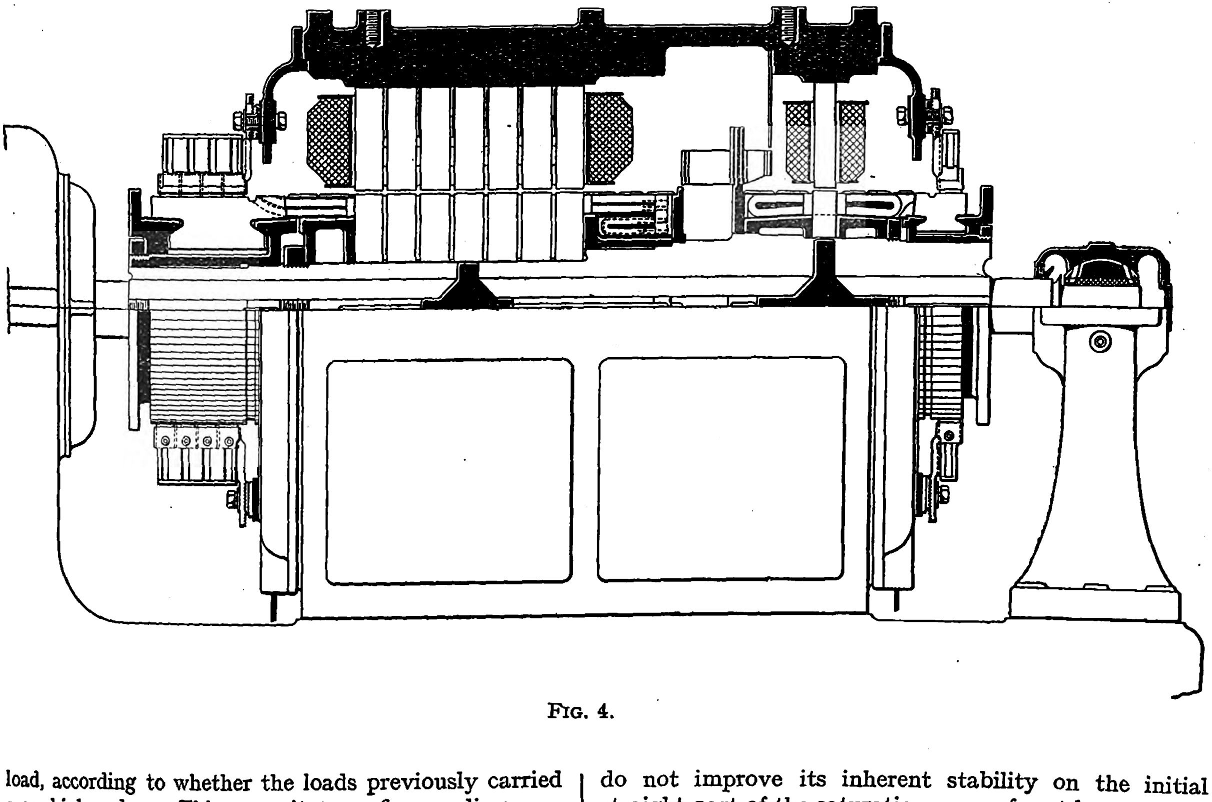

Fig. 4.

Series windings on the main poles of a shunt exciter do not improve its inherent stability on the initial straight part of the saturation curve, for at low voltages a pure series machine has the same range of instability as a shunt machine.

Exciter Response.

Definition.—The response of an exciter may be defined as the rate at which its voltage increases per second when the resistance in its field circuit is changed. Ultimately, in studying the complete alternator unit the response in exciter voltage must be translated into a response in alternator voltage.

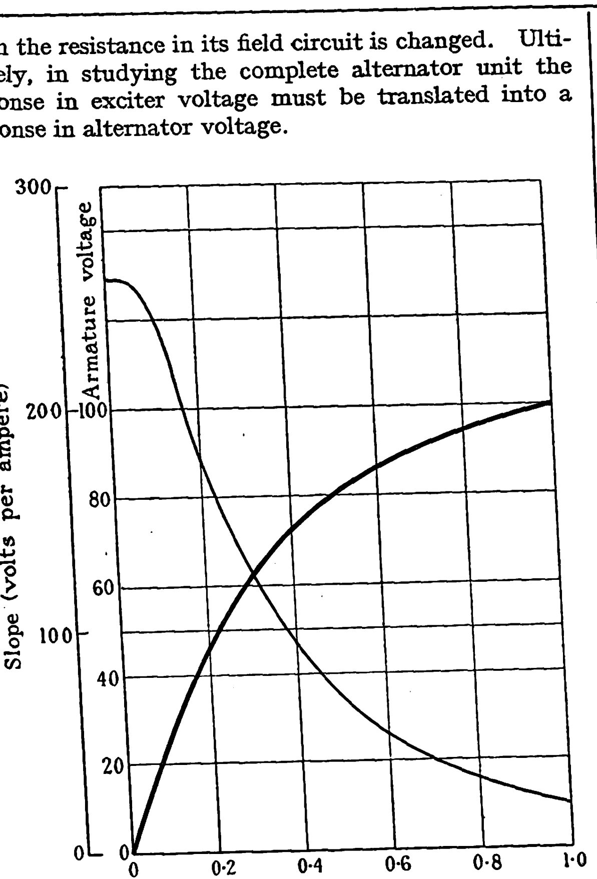

FIG. 5.—Typical exciter saturation curve.

The definition applies to the removal or the addition of resistance corresponding to rising or falling voltage, but, because the exciter voltage can be made to fall much more quickly than it can be made to rise, exciter response is considered throughout the paper with particular reference to the condition when all the exciter rheostat is short-circuited and the exciter voltage increases to the maximum possible value.

The response figure at any voltage is calculated by dividing the ultimate increase in exciter voltage by the time-constant of the exciter, the time-constant being defined as the time in seconds which the voltage would take to reach its final value if it continued to grow at the same rate at which it commenced to grow from the voltage in question. When saturation is present, the ultimate voltage in this definition is that which would be reached if the degree of saturation remained unchanged.

For a separately-excited exciter, the time-constant is calculated in seconds by dividing the self-induction of the exciter coils in henrys by the resistance in the exciter field circuit, a certain small time being added to allow for mutual circuits in the exciter field system, as explained later in the paper.

Comparison between Shunt-excited and Separately-excited Exciter.—In order to make the discussion general and the deduction applicable to all cases, a typical saturation curve is shown in Fig. 5, which gives a maximum voltage of 100 with an excitation of 1 ampere. Saturation curves, of course, vary in detail and designers may at times be tempted to run to a higher degree of saturation at the expense of an excessive field current, but this curve may be taken as representative if, for any actual case, a particular exciter voltage is reduced to a percentage of the maximum and the corresponding field current is reduced to a fractional part of its maximum. Fig. 5 also indicates degree of saturation at any excitation by giving a separate curve for volts per ampere. But for saturation such an exciter would give 260 volts at maximum excitation.

Again for the sake of generality in discussion, the time-constant of a typical exciter when working separately excited and unsaturated is taken as 1 sec.

Curve (a) in Fig. 6 shows the growth of voltage in this typical machine separately excited, when the field rheostat is changed to increase the voltage from 15 to the maximum value. If saturation were not present the exponential law would be followed, but because of saturation this curve is distorted at high voltages. The growth to the maximum from any other voltage may be obtained by moving the vertical axis to give zero time at that voltage.

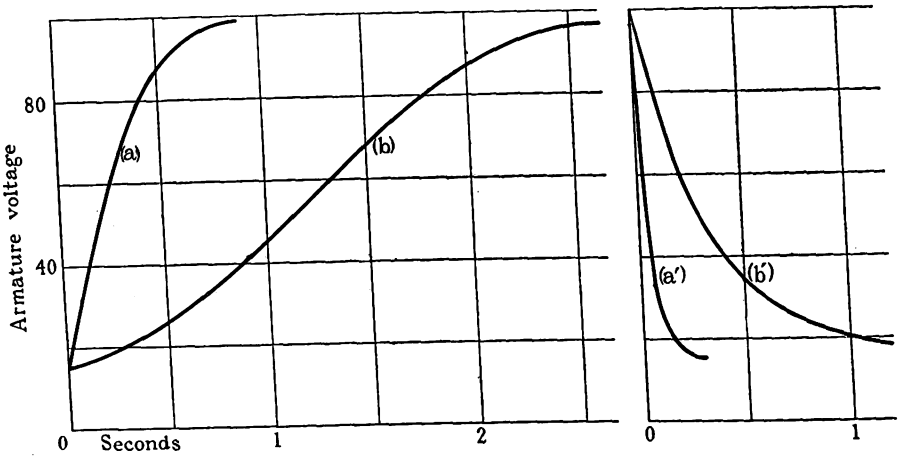

FIG. 6.—Growth and decay of voltage with shunt-excited and separately-excited exciters (exciter time-constant = 1 sec.).

The shunt exciter is slower than the separately excited machine in voltage growth and response as it depends for its exciting current upon its own voltage, which, at time of light load, is of relatively low value, whereas the separately excited machine has always a high, steady voltage with which to effect changes in exciter excitation.

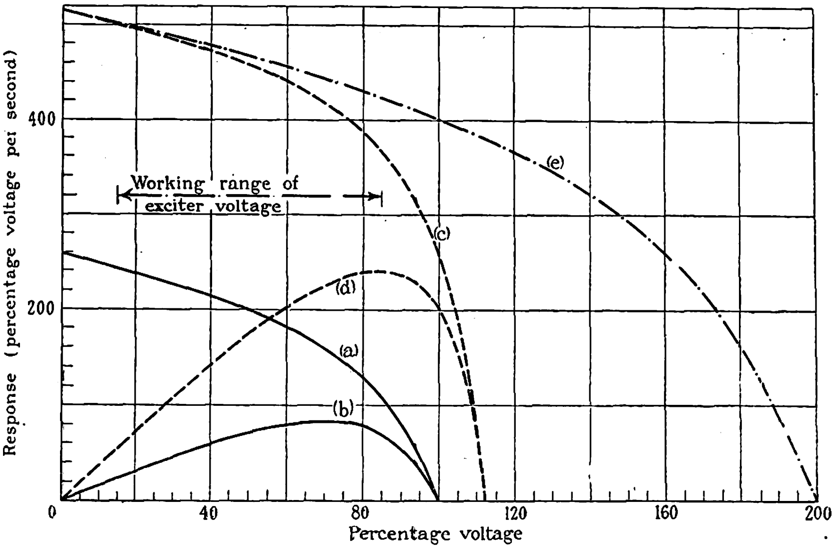

Fig. 7.—Voltage response of shunt-excited and separately-excited exciters (exciter time-constant = 1 sec.).

The growth of voltage from 15 per cent to maximum for the same typical exciter used as a shunt machine is shown as (b) in Fig. 6.

Curves (a′) and (b′) in Fig. 6 show the fall from maximum voltage when exciter field resistance corresponding to about 70 per cent of open-circuit alternator voltage is inserted. The exciter voltage falls away so quickly that a rise in alternator voltage after a reduction in load is easily prevented, and in the remainder of the paper only the response for an increase in load will be considered.

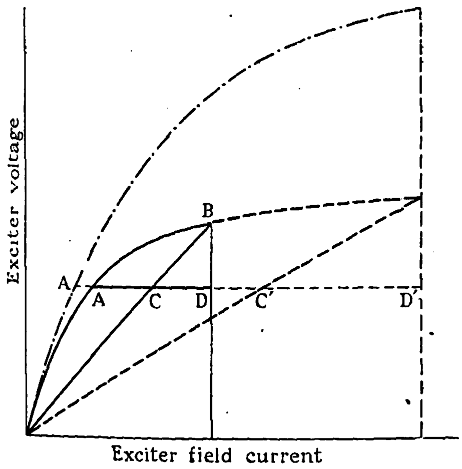

Fig. 8.—Graphical representation of exciter response.

The response curve at different voltages for the separately-excited exciter has been plotted in curve (a) in Fig. 7 from curve (a) in Fig. 6. At high voltages the total change in voltage is smaller, so that the response falls off as maximum voltage is approached. It is therefore desirable that the maximum available exciter voltage should be at least 15 per cent greater than that required for maximum excitation of the generator. The response for the same exciter when shunt-excited is plotted as curve (b) in Fig. 7.

It is interesting to show on a typical saturation curve how the responses for the two types of machine are related to one another. In Fig. 8, if B is the maximum possible voltage in both types of machine and A is any selected voltage, AC represents the response for a shunt machine and AD that for a separately-excited machine at this voltage.

Use of Curves for a Particular Exciter.—The growth and response curves in Figs. 6 and 7 have been based upon an exciter time-constant of 1 sec. for the unsaturated range of voltage and when the exciter is separately excited.

The time-constant of any exciter under these conditions can be calculated with fair accuracy from design data, so that values taken from Figs. 6 and 7 can be corrected for a longer or shorter time-constant as required. For instance, if the time-constant is 0·5 sec., a given voltage is reached in half the time shown in Fig. 6, and the response figures in Fig. 7 are twice as fast. From a machine-design point of view, the time-constant of an exciter is lower the higher the speed, but apart from this it seems to depend only upon the amount of loss which can be allowed in the field coils. As diameters become larger, it becomes more difficult to remove the heat from the more bulky field coils, although with turbo-alternator exciters the ventilation is very efficient. However, without exceeding a reasonable internal temperature in the centre of the cotton-insulated spool, a time-constant, as already defined, of 2·5 sec. can be obtained on the exciter for a 100 000-kW turbo-alternator running at 1 500 r.p.m., and 1·0 sec. for a 50 000-kW turbo-alternator running at 3 000 r.p.m.

Effect of Solid Poles, etc., upon Exciter Time-constant.—As metallic spool bodies and solid poles and magnet frame act as mutual circuits to the field spools and so may add appreciably to the time-constant calculated from the spools alone, it is well at this stage to review briefly the theory of mutual circuits in so far as it applies to the present discussion.

With a single self-inductive circuit, the flux grows simultaneously with the current in this circuit, but when a secondary circuit, although not in perfect mutual relation, is present, the flux grows in accordance with the sum of the currents in the two circuits, and in general its growth is retarded.

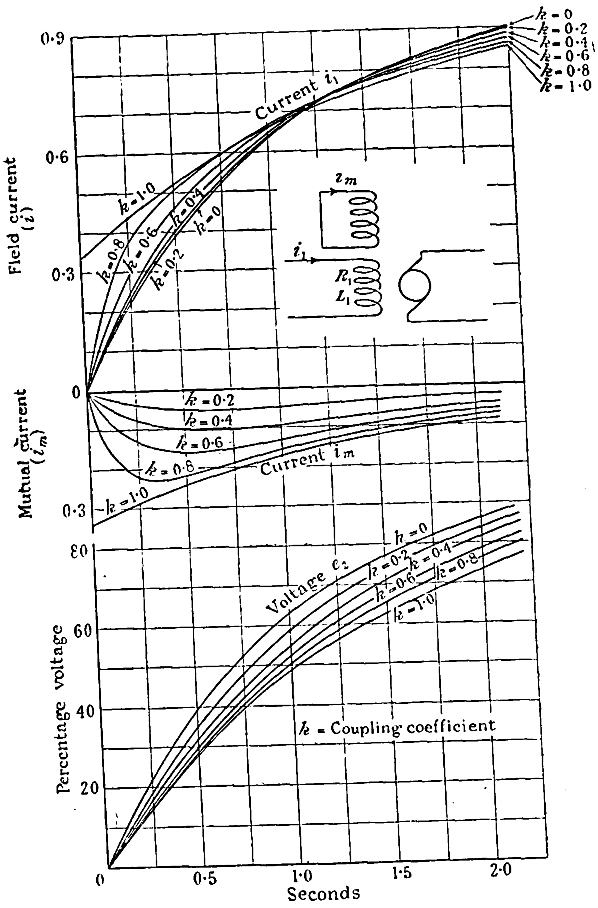

FIG. 9.—Growth of current and voltage in separately-excited exciter with a mutual field circuit.

When the secondary mutual circuit is short-circuited upon itself, a sudden initial growth of current will occur in the main circuit. However, this is a false current as regards generation of flux, as it will be opposed by a sudden growth of transient current in the secondary circuit.

The time-constant of the secondary circuit can be calculated in the same manner as the time-constant of the primary, and when the coupling between the two circuits is perfect the time-constant which determines the growth of the resultant flux is the sum of the time-constants of the two separate circuits.

When the coupling between the circuits is imperfect some intermediate rate of flux growth results. The growth is not truly exponential but is so nearly so that a time-constant sufficiently accurate for present calculations can be measured from an oscillograph record by taking 0·632 of the total growth of the exciter voltage over the unsaturated range.

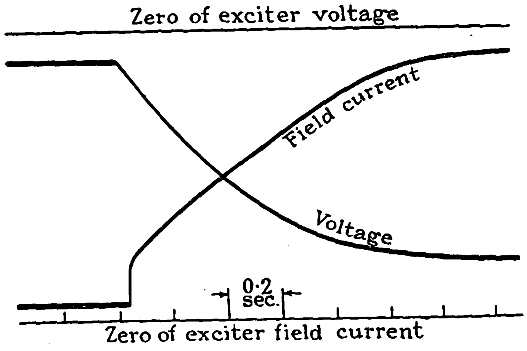

FIG. 10.

In order to illustrate this point, a set of curves has been plotted in Fig. 9 for a primary time-constant of 1 sec., a secondary time-constant of 0·5 sec. and for different coupling coefficients 0, 0·2, 0·4, 0·6, 0·8 and 1·0. Primary and secondary currents and resultant voltage growth are shown.

When the circuits are perfectly mutual, the initial opposed transient currents in both primary and secondary appear without any appreciable period of growth. This condition is found to exist between the mutual circuits of an exciter field system, and oscillograph records of growth of field current afford a means of discovering experimentally the relative importance of the mutual circuits or, alternatively, of checking calculations.

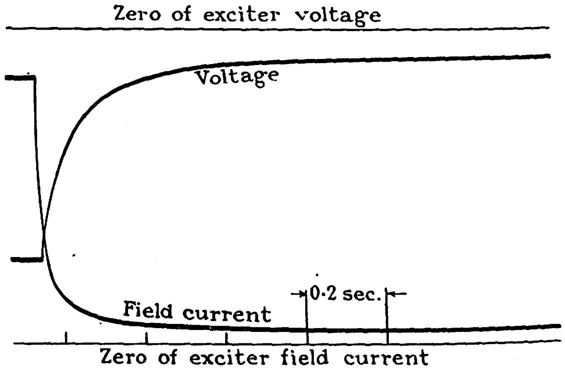

FIG. 11.

For instance, Fig. 10 shows oscillograph records of the rising field current and armature voltage of an exciter which, when the rheostat was short-circuited, showed a sudden change in exciter field current of 19 per cent of the total ultimate change, thus indicating an addition of 23·5 per cent to the time-constant for the field coils alone. Fig. 11 shows the falling curves when the rheostat is again connected in circuit. The field circuit then has a shorter time-constant, so that the mutual circuit which does not change becomes relatively greater. The sudden initial change of exciter field current is about 63 per cent of the ultimate change. Such curves as these are useful in determining how far mutual circuits have been eliminated from the design.

Another method of experimentally determining the values of time-constants of the main and the mutual circuits is to take two records of rising armature voltage, using a different resistance in the field circuit. This changes the time-constant of the field coils in inverse proportion to the total resistance of the circuit, the time-constant of the mutual circuit being included as a constant figure in each of the observations.

In the exciter for the 100 000-kW turbo-alternator already mentioned, a solid magnet frame would add 0·15 sec. to the time-constant, and solid poles would add another 0·15 sec.

To get the very best response from the exciter, having regard to magnetic dimensions to give its rating, it would be desirable to dispense with metallic supports upon which to mount the spools, and to laminate both the pole cores and the magnet frame.

Super-excitation.—By super-excitation is meant some means of securing quicker response than by converting to separate excitation the standard self-excited shunt machine, which has a margin of 15 per cent between the maximum voltage available and that required for maximum load on the alternator. The first step is to use a larger section of conductor with a correspondingly smaller number of turns for the field spools, or to provide a higher voltage for separate excitation so that a highly saturated condition will be reached in the exciter magnetic circuit when all the field resistance is removed. This procedure does not alter the time-constant of the exciter, but it increases the possible voltage-change. If, with the same field spools, the constant voltage for the exciter excitation is double its previous value, the response is double at the lowest voltage, and a constant value is added to the response at all other voltages within the working range. This condition of excitation as an extension of that previously considered is indicated by broken lines in Fig. 8, and at voltage corresponding to A on the saturation curve response for separate excitation is represented by AD′, and for shunt excitation by AC′. Response characteristics for both conditions are shown in Fig. 7, (c) and (d). This step in super-excitation is satisfactory if quicker response is desired without the necessity of over-exciting the alternator when heavy faults occur. A further step is to re-design the exciter so that in addition to providing excessive excitation in the field spools the magnetic circuit remains unsaturated at the voltage required for maximum alternating rating. This procedure will usually involve some sacrifice in the time-constant of the exciter, so that the response may be slightly less at low voltages, but it is higher at higher voltages and, in addition, it provides for a higher maximum voltage in an emergency.

In addition to the previously mentioned curves in Fig. 8, a saturation curve of an exciter is shown which has the same degree of saturation throughout its range as in a normal machine, but which has a maximum voltage of double the previous value with an excitation for this voltage which is also double the previous value in order to ensure the same degree of load stability.

Assuming, for the sake of standardizing the curves for future reference, that the time-constant of the re-designed exciter is still 1 sec., response is now indicated in Fig. 8 by A′D′ and the curve for response over the whole range of voltage has been added to Fig. 7 as curve (e).

It is not considered necessary to add a curve for a shunt machine to this design, in view of the poor inherent stability at the lowest voltage required for alternator excitation.

ALTERNATOR STABILITY.

Inherent Instability of Alternator.—If an alternator is connected to a circuit which consists largely of capacity, e.g. unloaded long overhead lines or underground cables, it may be self-exciting owing to leading current in the stator windings acting as a magnetizing current upon the magnetic circuit. The alternator will be inherently unstable in that the voltage may rise to a value which will be limited only by saturation.

A case sometimes occurs in high-potential testing when a smaller alternator is used to provide current for testing a large stator. On commercial circuits the effect has been noticed in some installations abroad. It is not likely to be as troublesome in England as, even when the country is linked together in one distribution network, the charging current will be small compared with the load current, which will contain a lagging as well as a power component. However, it is suggested that operating engineers, in specifying power factor for their machines, should include the capacity current required in distribution, and that manufacturers should base the stator dimensions upon kW rather than kVA rating and should use longer air-gaps when high power factors are specified.

In the same way that it is possible to say at what value of field resistance the shunt exciter will become inherently unstable, so is it possible to say at what value of external capacitance the alternator will commence to build up. In Fig. 12 an alternator saturation curve for the machine chosen later to represent typical present-day turbo-alternator practice is drawn to show, vertically, stator voltage as a percentage, and, horizontally, excitation in terms of stator current, as a percentage of the full-load value, having regard to the effectiveness of the armature windings carrying leading current. On a tangent drawn through the initial part of the saturation curve the excitation for 100 per cent voltage corresponds to 53 per cent full-load current. A capacity corresponding to this current and voltage is the limiting value which will cause self-magnetization, and the voltage would then rise to about 65 per cent of normal. Fig. 12 also shows that if the line capacity corresponds to full-load current at normal voltage, the alternator will self-magnetize itself to 36 per cent above normal value.

Load Instability of Alternator.—When capacity is absent or negligible, and with a constant excitation, load conditions produce a drop in voltage and, according to the nature of this load, the alternator may be unstable. If the load is of such a character that the drop in voltage is followed by a corresponding drop in load current, as may occur with a purely lighting load, a steady but reduced voltage will result. On the other hand, if the kVA demand remains the same with falling voltage as, for instance, with an induction-motor load, it may be that an additional load cannot be sustained and the alternator voltage falls to zero if the excitation of the alternator is not adjusted, preferably by automatic means, as soon as the changed load conditions affect the alternator voltage. The usual condition of service is probably intermediate between these two, corresponding approximately to a synchronous-motor load in which there is a constant power demand but in which the wattless demand diminishes somewhat with falling voltage.

Trend in Turbo-alternator Design.—An alternator is often judged in regard to its stability either by the ratio of the armature reaction expressed in ampere-turns at full load to the field ampere-turns at no load, or by the ratio of field current required for normal stator voltage with the terminals open-circuited to the field current to produce steady full-load current with the stator windings short-circuited. The former method classifies the machine from the point of view of the designer, who includes in his consideration the percentage reactance as well as the percentage armature reaction, while the latter method is more suitable from the operator's point of view and gives what is termed the "synchronous reactance" of the alternator, 100 per cent synchronous reactance meaning that the same excitation is required for normal voltage on open circuit as for full-load current on steady short-circuit.

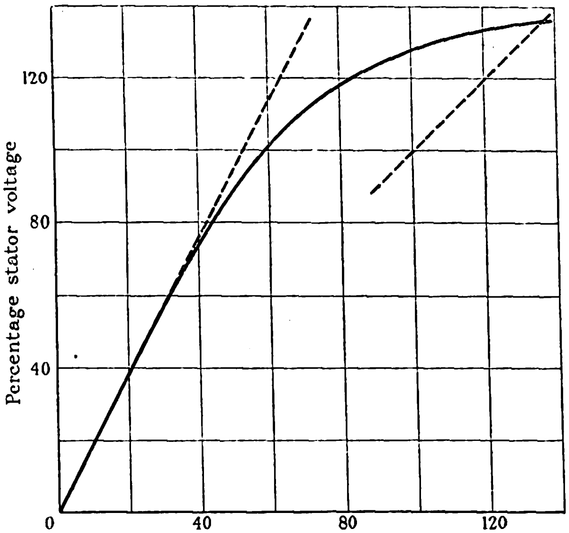

FIG. 12.—Building-up of stator voltage with capacity load.

When turbines came into use about 25 years ago the design characteristics of the alternator which they drove were the same as those of salient-pole machines as then built. Such machines had a reactance of 8 per cent and an armature reaction of 65 per cent, and gave on test a synchronous impedance of, say, 73 per cent. The tendency in turbo-alternator design, however, has been to design with higher armature reactions, and nowadays typical figures for machines built in England and on the continent of Europe are reactance 16 per cent and armature reaction 160 per cent, giving a synchronous reactance of 176 per cent. These characteristic figures apply to machines designed to work at 0·8 power factor.

In America, designs have not such high percentages of armature reaction, but some machines with figures even in excess of these have been in successful operation for some years on large systems in England. The evolution has taken place gradually over the whole period of turbine development, partly as the result of a search for a design which will be cheaper per unit of rating, and partly in keeping pace with the art of turbine design, for the large ratings now being built at the higher speeds would be impossible for mechanical reasons if the electrical design characteristics of even 10 years ago had to be used.

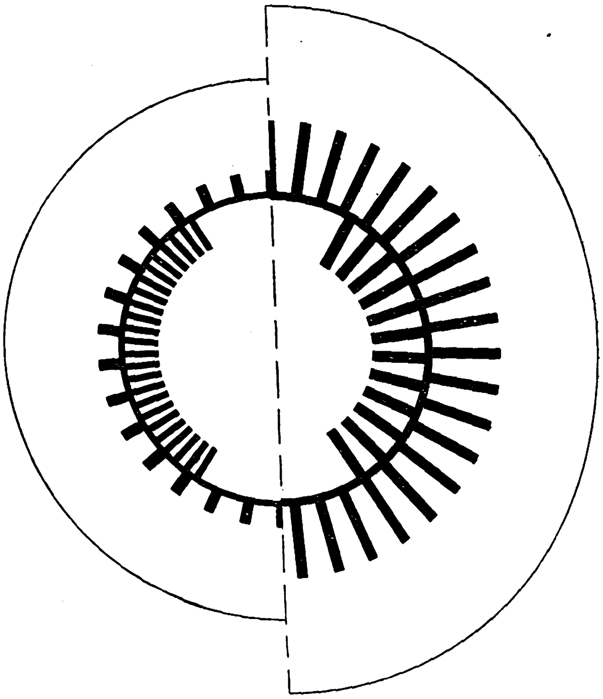

FIG. 13.—Two-pole designs dated 1908 (left) and 1928 (right).

In design language, the turbo-alternator has become more a "copper" machine and less an "iron" machine, and a comparison of the two diagrammatic cross-sections of slots and cores in Figs. 13 and 14 will show what is meant by this statement. For the purpose of comparison, old and up-to-date designs for both 2 and 4 poles have been chosen, the comparative sections having been so drawn as to have the same stator-face diameter. Fig. 13 shows a modern 2-pole design, in comparison with one from which machines were built in 1908. Again, Fig. 14 shows a modern 4-pole design and a design in use in 1910. In both cases the up-to-date design shows deeper slots and, therefore, contains a larger cross-section of copper, the result of which appears as a higher rating for the same length of core.

Performance Characteristics of a Modern Turbo-alternator.—Curves of excitation for open circuit (saturation), short-circuit (impedance) and load at unity and 0·8 (lagging) power factors on a machine which has been taken as a design typical of the present time are shown in Fig. 15, normal voltage, maximum load current and excitation for normal voltage on open circuit all being taken for the sake of generality as 100.

It will be seen that maximum load at 0·8 power factor requires 2·63 times the excitation for open-circuit normal voltage, and if we assume a temperature-rise of 90 deg. C. on the rotor-winding copper as measured by resistance between no load and full load, the exciter will need to be stable over a range of 1 : 3·5. With a margin of 15 per cent between the maximum excitation voltage required and maximum exciter voltage available, it appears that a shunt exciter must be stable at 24 per cent of its maximum voltage.

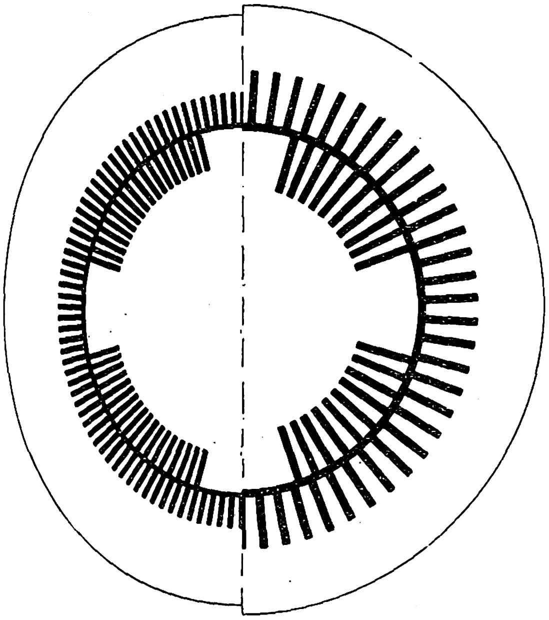

FIG. 14.—Four-pole designs dated 1910 (left) and 1928 (right).

The inherent voltage regulation of an alternator is defined as the voltage-rise which will occur when full load is thrown off, excitation remaining constant at full-load value. With the older type of machine, for a power factor of 0·8 this was usually guaranteed to be not more than 22 per cent, but with the present-day machine this figure has risen to approximately 45 per cent. The corresponding figures of voltage-drop, when the full-load circuit is suddenly connected to the alternator terminals, are about 30 per cent with the older machines and about 60 per cent with the present-day machines. In either case the voltage variations between no load and full load, and vice versa, are altogether too wide for satisfactory service without automatic regulation, but, on the other hand, full load is never thrown on or off, and, as pointed out in the introduction, incidental variations of load are becoming smaller in relation to the capacity of the machines.

The performance characteristics of the modern turbo-alternator are further developed in a family of load saturation curves at 0·8 lagging power factor for $\frac{1}{5}$, $\frac{2}{5}$, $\frac{3}{5}$, $\frac{4}{5}$ and full load at normal voltage in Fig. 16. From these, a family of volt-ampere curves, each for a constant excitation, corresponding to one of the loads calculated for Fig. 16, can be derived as in Fig. 17.

In this form, characteristic curves are useful in determining the change in voltage which would follow a change in load. The positions on the various curves corresponding to normal voltage are shown as dots, and through these radial lines are drawn from the origin. Each of these radial lines represents an impedance corresponding to the particular fractional load for which it is drawn at normal voltage, so that if the machine is working at, say, 40 per cent load and another 20 per cent load is thrown on, then the voltage will fall along the volt-ampere characteristic for 40 per cent load excitation until this curve cuts the radially drawn impedance line for 60 per cent load, provided the load is such that the impedance does not change with voltage. This occurs at 87 per cent normal voltage and 52·2 per cent normal current. If, still without changing the excitation, the load circuit is changed to correspond to another 20 per cent rise in load, the voltage will fall, still along the same volt-ampere characteristic, until it meets the next radial line drawn in the diagram. The voltage will then become steady at 75·5 per cent of normal voltage and the current which is being carried will be 60·5 per cent of full-load value.

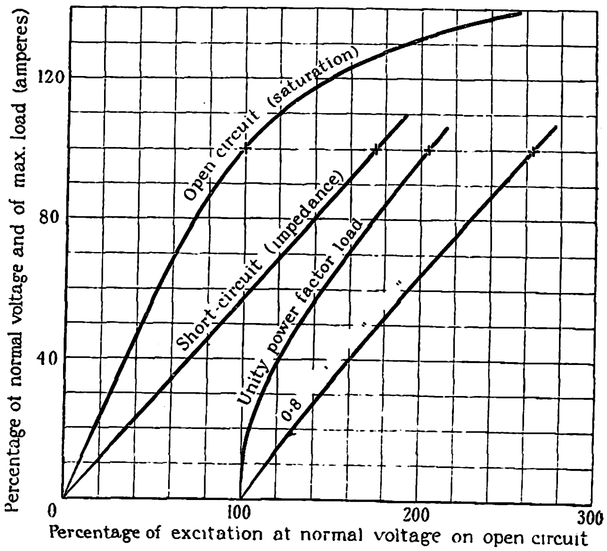

FIG. 15.—Characteristic curves of typical turbo-alternator.

When the load circuit is changed to a much lower impedance, say one corresponding to 40 per cent above the maximum rated load, the voltage will still settle down to a steady but lower value, namely, 51·5 per cent of normal, the current being 72 per cent of maximum load value. It is therefore apparent that, under this condition of loading, the machine is stable and that it does not entirely lose its voltage until the terminals become short-circuited.

In order to illustrate the performance for the other extreme condition of loading, i.e. when the kVA remain constant in spite of falling voltage, rectangular hyperbolæ have been drawn in Fig. 17. The first curve of this kind, drawn through a point representing 20 per cent load at normal voltage, just touches the volt-ampere characteristic for no-load excitation, and from this we conclude that, under these conditions of load, if 20 per cent load is thrown on with the machine at no-load excitation, a steady voltage will be reached where the two curves touch one another, viz. at 64 per cent voltage and 31·5 per cent current. If, however, the circuit is changed to correspond to a higher load at normal voltage, the excitation still remaining constant as for normal voltage on open circuit, the corresponding constant kVA curve will not touch or cut the volt-ampere curve for no-load excitation, so that the alternator will completely lose its voltage and, therefore, may be said to be unstable when load of this character beyond a certain value is thrown on.

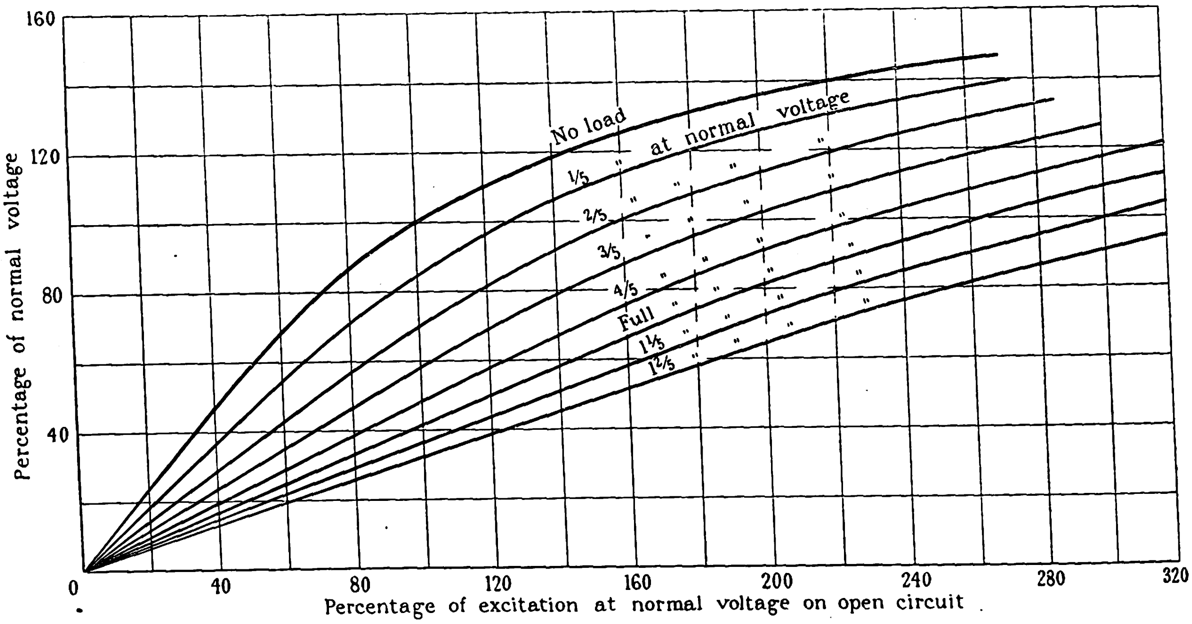

FIG. 16.—Load saturation curves at 0·8 power factor.

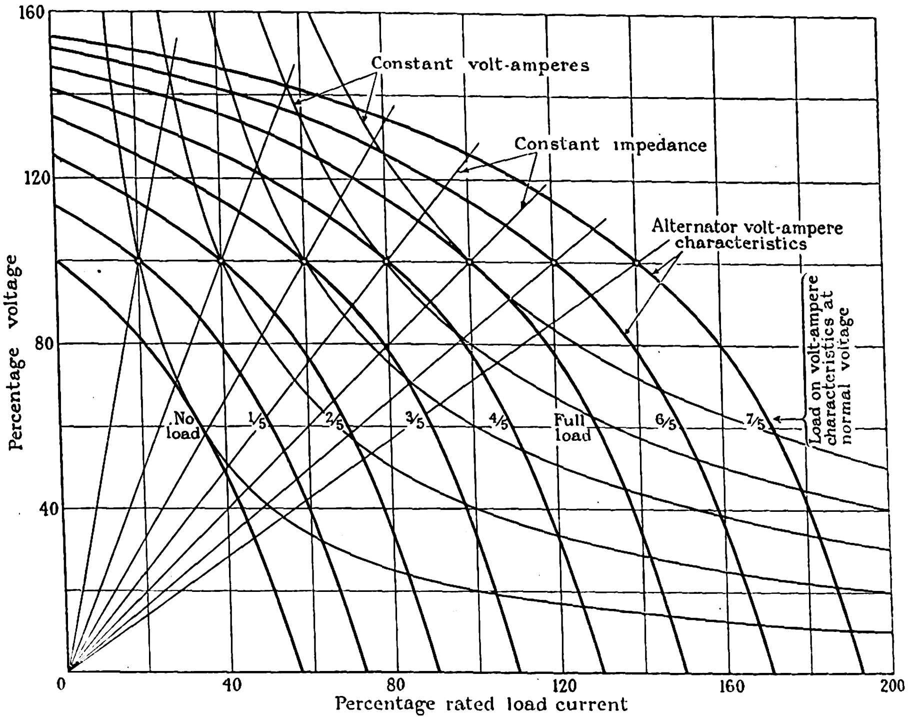

FIG. 17.—Volt-ampere characteristics of alternator for various constant excitations (0·8 power factor).

An inspection of the other curves will show that the capacity for higher loads of this character becomes less and less as the alternator voltage is brought back to normal after each change in load. At maximum load, as the two types of curves are practically tangential to one another at normal voltage, there is no margin for further loading of this character unless the excitation is increased. However, there is no doubt that, with falling voltage, load does not follow constant kVA but rather constant kW with a wattless component of current proportional to the voltage. Moreover, the inertia of the alternator magnet-system prevents the voltage from falling unduly before the excitation circuits can be changed, so that an alternator may be said to be stable conditionally upon an adjustment being made in the excitation circuit.

ALTERNATOR RESPONSE.

Alternator Reactance and Armature Reaction.—The voltage-drop in the alternator voltage when load is thrown on is calculated in two steps.

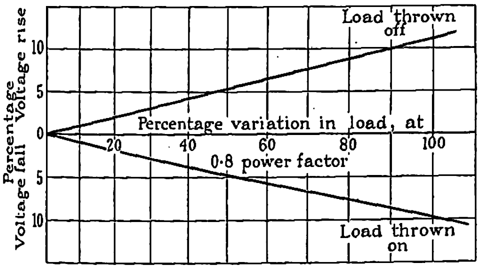

FIG. 18.—Reactance voltage-change at different loads.

The first involves the reactance of the stator windings and assumes that constant voltage is available for this reactance in series with an impedance corresponding to the load, and the calculation consists in determining the different percentage voltage absorbed in the stator reactance before and after the load-change.

The reactance voltage-rise or fall, as the case may be, for percentage changes of 0·8 power-factor load for a machine with 16 per cent reactance is shown in Fig. 18. When full load is thrown off, the voltage-rise due to this cause is 11 per cent; or if full load is thrown on when the machine is on open circuit the voltage-drop is 9·8 per cent. As the time-constant of a load circuit of normal power factor is very small, the change in load current, and therefore the change in voltage at the alternator terminals due to reactance, occur very quickly, in fact practically simultaneously with the change in the load-circuit conditions.

The second part of the calculation takes account of the magnetizing effects of the opposing stator and rotor currents, and each change in load produces a change in the main flux of the machine and therefore in the machine voltage.

The main flux of the machine has an appreciable time-constant, so that this change in voltage takes place slowly. Without any change in the excitation circuit, a change in rotor current occurs simultaneously with a change in the stator load current. Thus the flux is maintained at the instant the load-change takes place. The rotor current then gradually returns to its former value as the new stator current becomes effective in changing the main flux of the machine.

A fraction of the total voltage-change, therefore, is in evidence as soon as the load conditions change, but the remaining portion of the voltage-change takes an appreciable time, and with a quickly responsive exciter this time is long enough, especially if an automatic regulator is used to change the excitation-circuit conditions to allow the exciting current to be adjusted to the new value required for the new load. The voltage variation in the transient period during which it is being restored to normal value after a change in load, is considered in the section dealing with "Combined response of alternator and exciter."

An interesting example of the transient variation in field current when a change in load conditions causes a change in flux is shown in Fig. 19. This is an oscillograph showing the stator voltage and the exciting current of an alternator from the instant of the opening of a switch which was short-circuiting the stator windings. At this instant, a voltage corresponding to the voltage previously absorbed by current flowing through the reactance of the short-circuited windings suddenly appears at the stator terminals, and at the same time the exciting current drops to that corresponding to this voltage, although the exciter voltage remains constant. The fall in exciting current is not so sharp as the rise in

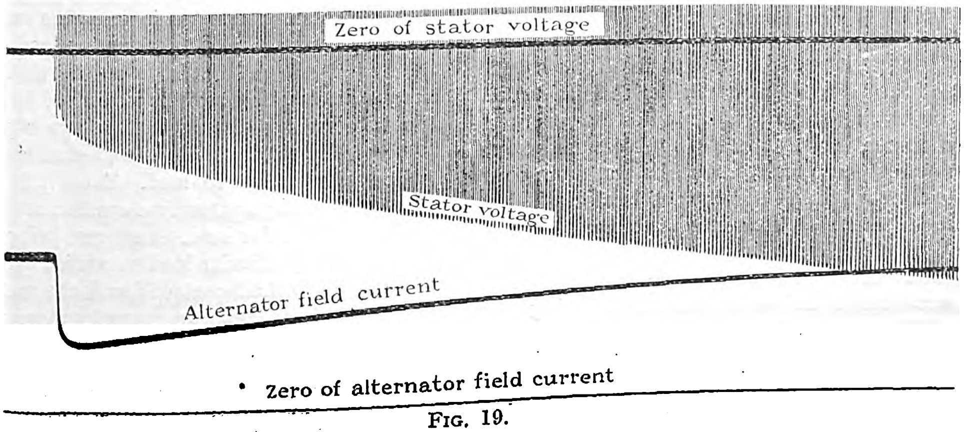

FIG. 19.

voltage, because of the presence of mutual circuits, but after a few cycles both rotor current and armature voltage rise together, the former to its previous value and the latter to a voltage corresponding to the rotor current when the stator is on open circuit.

Alternator Time-constants on Open Circuit.—If excitation corresponding to 25 per cent in excess of normal voltage were suddenly switched on, the form of curve for the growth of alternator voltage would be similar in shape to that given in curve (a) in Fig. 6 for a separately excited exciter. The actual time of growth of the voltage to the maximum value would be longer, in fact probably about 10 times as long, because the time-constant of the alternator would be longer than for the exciter. The growth for large alternators would be slower than for small alternators.

From a design point of view the time-constant of turbo-alternators with characteristics as previously described depends principally upon the diameter and the number of poles, and is almost independent of the length of core. As the maximum permissible rotor diameters as determined by the mechanical properties of the steels at present available seem to have been nearly reached, larger outputs are being obtained by lengthening the active core of the machine. The time-constants for the large sizes of turbo-alternators thus seem to have assumed a uniform value, and for both 3 000-r.p.m. and 1 500-r.p.m. 50-cycle machines, designed with the characteristics already described, the time-constant with the magnetic circuit unsaturated and based upon conductive material in the rotor windings alone is about 10 sec.

However, the rotors of all 3 000-r.p.m. machines and of many 1 500-r.p.m. machines are made from a single forging, and this adds a considerable section of mutual current-carrying material which becomes effective when a flux change is taking place. Thus the solid mass of the rotor core adds about 4 sec. to the time-constant of a 1 500-r.p.m. machine, and about 2 sec. to that of a 3 000-r.p.m. machine. In the alternative 1 500-r.p.m. construction, in which separate plates about 3 inches in thickness are mounted on a central shaft, the additional time-constant due to this cause is negligible. The importance of the solid conducting section of steel in the solid rotor body may be judged by observing the relative sections of copper and steel in Figs. 13 and 14, it being remembered that the conductivity of the steel is only 20 per cent of that of the copper.

The coupling coefficient between the coils and core of a solid 3 000-r.p.m. rotor was investigated by associating the oscillograph test referred to in Fig. 19 with a set of calculations as plotted in Fig. 9. The difference between the observed rise in voltage and the observed change in field current represents the equivalent current in the mutual circuit. A calculation of the time-constants of the exciter windings and the solid rotor enabled a set of curves of secondary or mutual currents to be calculated and plotted for different degrees of coupling. The curve which corresponded in shape to the experimentally deduced curve indicated that the coupling was of the order of 75 per cent.

The adjustment of flux in the alternator at different loads does not take place, as in the exciter, over the wide range between practically zero value and the highest point of the saturation curve, and for this reason it is only necessary to consider the time-constant of the alternator at normal voltage.

The partial saturation of the magnetic circuit of the alternator at normal voltage and on open circuit will be found to give a slope to the saturation curve at this point, expressed as volts per ampere, of about 60 per cent of that for the unsaturated portion. In making response calculations on no load, e.g. when all load on the machine is thrown off, the time-constants for large 50-cycle turbo-alternators may therefore be taken as 7·2 sec. for 3 000-r.p.m. machines, 6 sec. for 1 500-r.p.m. machines of the plate-rotor construction, and 8·4 sec. for 1 500-r.p.m. machines of the solid-rotor construction.

Alternator Time-constants on Load.—The flux-changes from one load to another being relatively small, adjustments of field current, of which a wide range is required in modern turbo-alternators, are concerned chiefly in counterbalancing changes in armature reaction due to the varying load. With increasing load, for instance, the stator current tends to reduce the flux, and an increase in exciting current is required to bring it back to a value which gives normal voltage at the terminals. In effect, this changes the time-constant of the alternator with every change in load. Thus, it is necessary to determine the alternator time-constant at normal voltage for each particular load, due regard being given to the slope of the particular load saturation curve at normal voltage and to the increased flux in the machine required at this load to maintain normal voltage at the stator terminals.

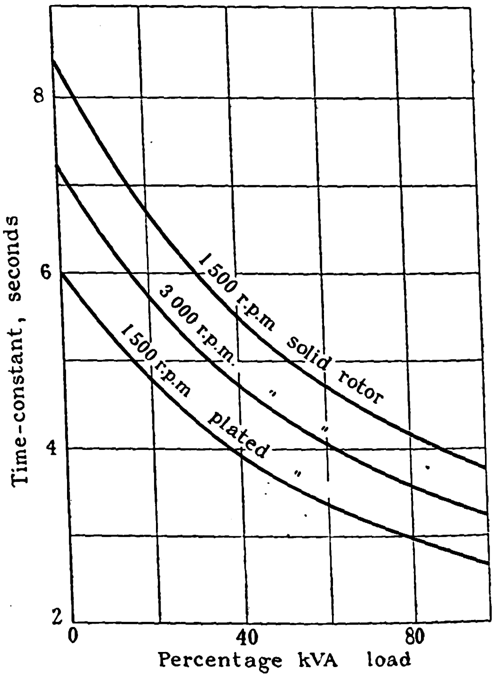

FIG. 20.—Alternator time-constants at different loads (0·8 power factor).

The curves in Fig. 20 show the time-constants on load for the different types of machines when working at 0·8 power factor. An allowance has been made for the higher temperature of the rotor coils at higher loads and for increased leakage at the higher excitations.

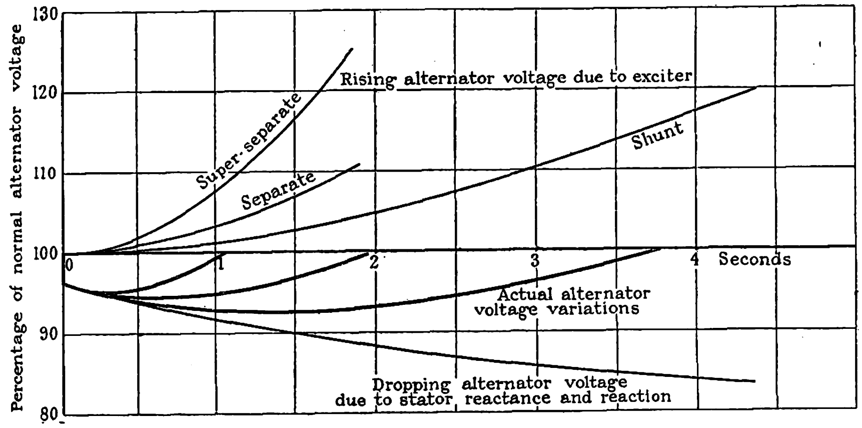

FIG. 21.—Restoration of voltage after increasing load suddenly from 40 per cent to 80 per cent (power factor 0·8) with different methods of exciter excitation.

Alternator Response.—A knowledge of the time-constant and the regulation of the alternator on load allows a curve to be drawn of falling voltage when load is thrown on. As already pointed out, such a curve consists of an initial sudden drop due to the reactance (see Fig. 18), followed by a gradual change to a value which may be determined from Fig. 17. It is sufficiently accurate for present purposes to assume an exponential variation during the latter change corresponding to the time-constant given for the new condition of load in Fig. 20; and the character of the voltage-drop of a solid-type 1 500-r.p.m. turbo-alternator, already carrying 40 per cent load, when another 40 per cent load is suddenly thrown on is shown in Fig. 21. This curve represents the response of the alternator alone, i.e. if the excitation circuits are not adjusted. The assumption has been made that the load-circuit impedance does not change with falling voltage and, even if this assumption is not strictly true, the combined response of alternator and exciter as studied in the next section will not be much affected, as the voltage variation from normal is then relatively small.

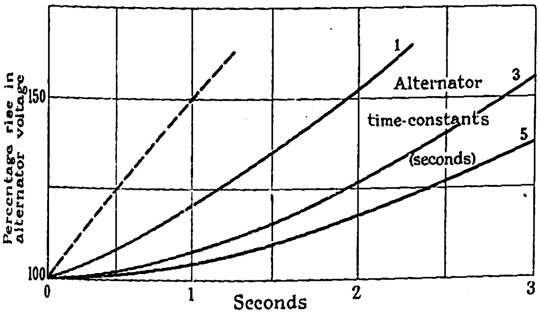

FIG. 22.—Delay in growth in alternator voltage after exciter response.

COMBINED RESPONSE OF ALTERNATOR AND EXCITER.

Voltage regulators operate upon the exciter field circuit rather than directly upon the alternator field circuit, because it is not practicable to manipulate contacts carrying the large exciting currents of the latter. As soon as an increase in load causes an appreciable voltage-drop the regulator should short-circuit the exciter field rheostat and continue to do so until normal alternator voltage is restored. In combination, the response of the alternator waits upon the response of the exciter, and an accumulative delay occurs in the restoration of the normal alternator voltage. For instance, suppose that under certain conditions the exciter voltage responds at a rate which corresponds to an increase in the alternator voltage at the rate of 50 per cent per second, as indicated by a dotted line in Fig. 22; then if the alternator has a time-constant of 5 sec. the actual

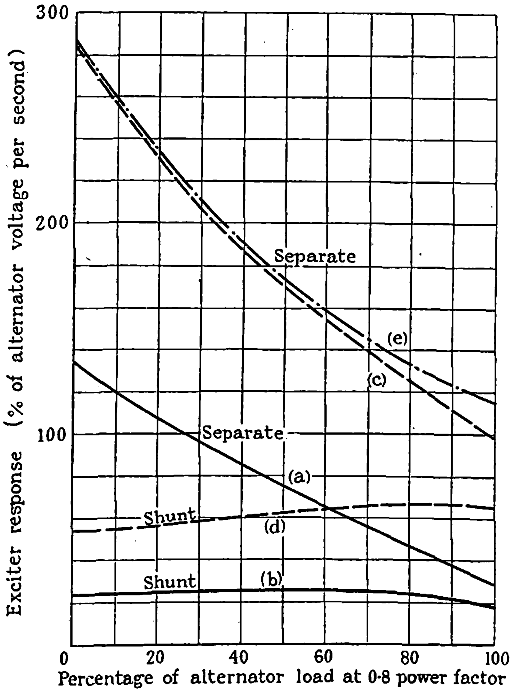

FIG. 23.—Exciter response in terms of alternator load and voltage (exciter time-constant = 1 sec.).

growth of alternator voltage is shown by the full line in the figure.

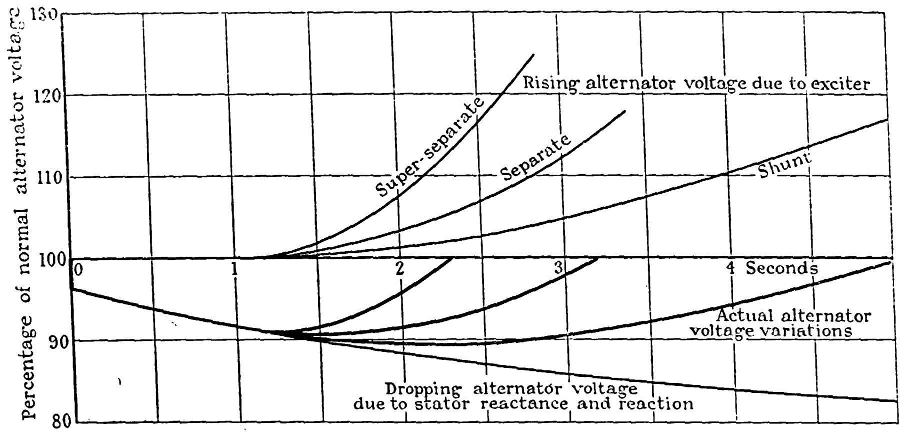

FIG. 24.—As Fig. 21, but with action of regulator delayed by 1 sec.

In order to make calculations of the combined response of exciter and alternator, it is convenient to convert the curves in Fig. 6, which show exciter response in percentage exciter voltage per second at any given exciter voltage, into the corresponding percentage alternator voltage per second at any given alternator load. Thus the abscissæ of Fig. 7 shown as percentage exciter voltage can, by reference to the abscissæ of Fig. 16, be converted into percentage alternator load, and, assuming full alternator load to correspond to 85 per cent of exciter voltage, and taking account of increased temperature of rotor windings on load, the ordinates in Fig. 7 can be converted into percentage of alternator voltage per second having regard to the slope of the particular load saturation curve of Fig. 16 which applies. The result is shown as Fig. 23, the ordinates, however, requiring correction, as did those of Fig. 7, for the particular exciter time-constant.

In calculating the combined response of alternator and exciter it is sufficiently accurate to take from Fig. 23 the average exciter response in terms of alternator voltage in the given change in load, and to associate this with the alternator time-constant for the new load as obtained from Fig. 20. By this means, upon a change in load and with the exciter rheostat short-circuited, a curve of rising voltage can be plotted in Fig. 21 on the supposition that the increased alternator reaction for the new load is not effective.

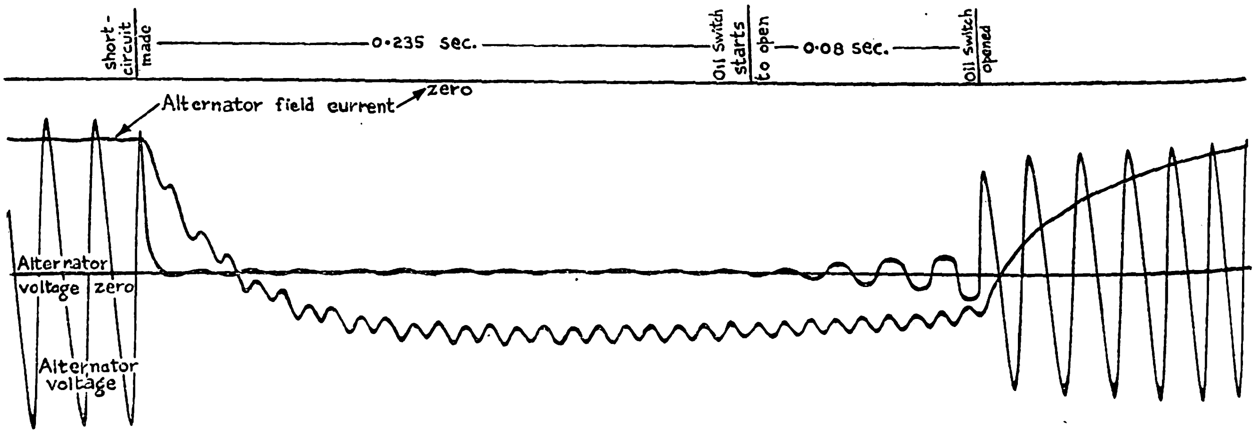

FIG. 25.—Sudden single-phase short-circuit on 4 000-kVA turbo-alternator.

Three such curves are given in Fig. 21 for the change of load conditions already considered for alternator response alone. One curve is for a shunt exciter, the second is for the same exciter separately excited, while the third is for super-excitation of the same machine at twice the exciter voltage.

We have now calculated (1) the drop in voltage due to armature reaction when the exciter does not respond, and (2) the rise in alternator voltage due to the exciter if armature reaction were not effective.

We assume that the actual cycle of voltage variation after a change in load is the addition of the rise on the one curve to the fall on the other. Such average curves have been drawn as thick lines in Fig. 21 and show a maximum voltage-drop of 8 per cent and a time of 3·8 sec. to restore the voltage completely to normal again in the case of the shunt exciter. For separate excitation the figures are 5·5 per cent voltage-drop and 1·8 sec. for restoration, and for super-excitation 4·5 per cent drop and 1·0 sec.

The vibrating-contact type of regulator provides for different exciter voltage at different loads by allowing its contacts to remain closed for a relatively long time at high loads and a relatively short time at low loads. For such a gradual increase in load as does not cause much alternator voltage variation the change in the character of the beat, that is to a longer period of junction of the contacts with a shorter time of break between periods of contact, is also gradual and the average value of alternator field current increases with the load. With sudden increase in load and wider variation in voltage it is necessary, in order that the middle curves in Fig. 21 may be obtained, that the regulator should short-circuit the exciter field rheostat as soon as possible after load is thrown on. This is effected in the vibrating-contact type by a cessation in the beating of the contacts. Any hesitation in the regulator in doing this will appreciably lengthen the time before voltage is restored and appreciably increase the maximum voltage-drop which will occur during this period. In effect, the upper curves of Fig. 21 will be displaced a certain distance to the right. If the delay is, say, 1 sec., the curves of Fig. 21 take the form shown in Fig. 24.

Again, because of the lagging of the alternator response behind the exciter response, the exciter voltage will temporarily overshoot the value required for the new load, but as soon as alternator voltage is restored the regulator should commence beating in a suitable manner for the new load.

Another type of sudden load application is a short-circuit on the machine. If this is in the neighbourhood of the busbars, while the short-circuit lasts it will cause the alternator voltage to disappear completely. The usual protective devices installed to disconnect the lines associated with a fault are expected to remove the short-circuit in a fraction of a second. Upon removal, a large fraction of the alternator voltage, corresponding approximately to the extent to which the high initial current associated with a sudden short-circuit has fallen, will reappear. This point is illustrated in Fig. 25, which is drawn from the oscillograph record of stator voltage and field current on a 40 000-kVA turbo-alternator before, during and after a sudden single-phase short-circuit. When the short-circuit is removed after approximately 0·3 sec. the voltage reappears at 70 per cent of its full value.

The time-constant of a large turbo-alternator under short-circuit conditions is approximately 1 sec., and Fig. 26 shows the percentage reappearance of voltage after various durations of short-circuit. The curves have been drawn truly exponential, but a consideration of tests such as shown in Fig. 19 indicates that rather larger voltages than indicated appear after short-circuits of comparatively long duration.

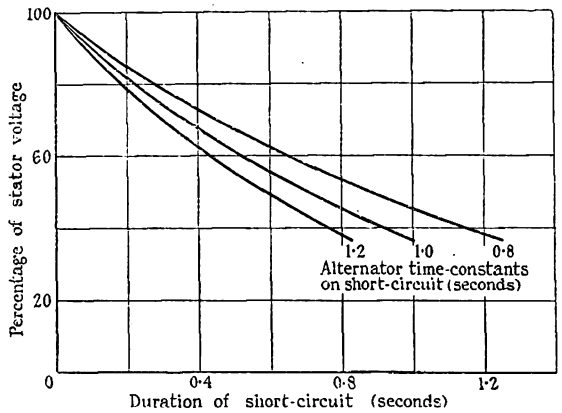

Fig. 26.—Reappearance of stator voltage upon removal of short-circuit.

Reverting to Fig. 25, the presence of the mutual circuits in the alternator rotor body is indicated by a relatively slow adjustment of rotor current at short-circuit and after the short-circuit is cleared.

The author desires to thank his colleagues on the engineering staff of the British Thomson-Houston Co. for helpful criticism and suggestions.

Discussion before The Institution, 28th November, 1929.

Mr. J. A. Kuyser: I should like to support the proposal to use what the author calls the "service exciter." By means of this exciter it is possible to obtain greater stability than by any other means. In many cases generators have to operate by themselves, and small variations in the contact between the brushes and the commutator may cause voltage fluctuations. In other cases exciters are operated at very low voltages, due to the fact that the alternator is operated at a higher power factor than that for which it was designed. In all these cases a service exciter would be of great assistance. Another suitable application is where a house alternator is used which supplies current to the auxiliary motors. These motors are often large compared with the generators, so that when a motor is started up there will be a large voltage-drop and other motors will be tripped. A service exciter in connection with an automatic voltage regulator will give the necessary quick response and will help to maintain the voltage. In connection with the design of the service exciter, we have been using a type of exciter of somewhat different mechanical construction. The first point of difference is in the field system. This is made throughout of cobalt steel, which gives the advantage of a constant flux and also eliminates the fine-wire field-winding. Another modification is that the service exciter is run at a low speed of about 750 r.p.m., and is driven from the governor of the steam turbine. The lower speed results in increased reliability. In order to obtain the maximum possible stability from the service exciter, it is of advantage to introduce some magnet steel in the magnetic circuit of the main exciter. We have been using a cobalt-steel plate placed between the poles and the yoke, which is proportioned to give from 10 to 12 per cent residual voltage. With reference to the arrangement shown in Fig. B, by the use of a short saturated path reasonably good results can be obtained if the magnetic section is reduced to about 15 or 20 per cent of the pole section, and the length of this path is made about 2 or 3 times the length of the air-gap. Fairly good stability is obtainable by this method, but the disadvantage is that a very large number of ampere-turns are required in the field coils.

Fig. A.

It is also necessary in this case to use a small series winding to prevent reversal of the exciter polarity. This series winding is not necessary if the magnet-steel plate is used. In connection with the general problem of stability, exciter stability has not to my knowledge been properly defined. I would propose that stability be defined as the ratio between the change in speed and the corresponding change in voltage. If we accept this as a definition, the stability can be easily determined from the saturation curve. It can be shown that by drawing a tangent at the saturation curve and prolonging this to meet the vertical axis (see Fig. A), the ratio a/b is equal to the exciter stability. I have plotted some curves on this basis; they give the stabilities of the different arrangements of exciters (see Fig. B). The horizontal line at the top represents 100 per cent stability, which can be obtained by energizing the exciters from a battery. It is interesting to note that the service exciter in combination with a normal main exciter gives, at low voltages, less stability than the self-energized exciter containing a magnet-steel plate.

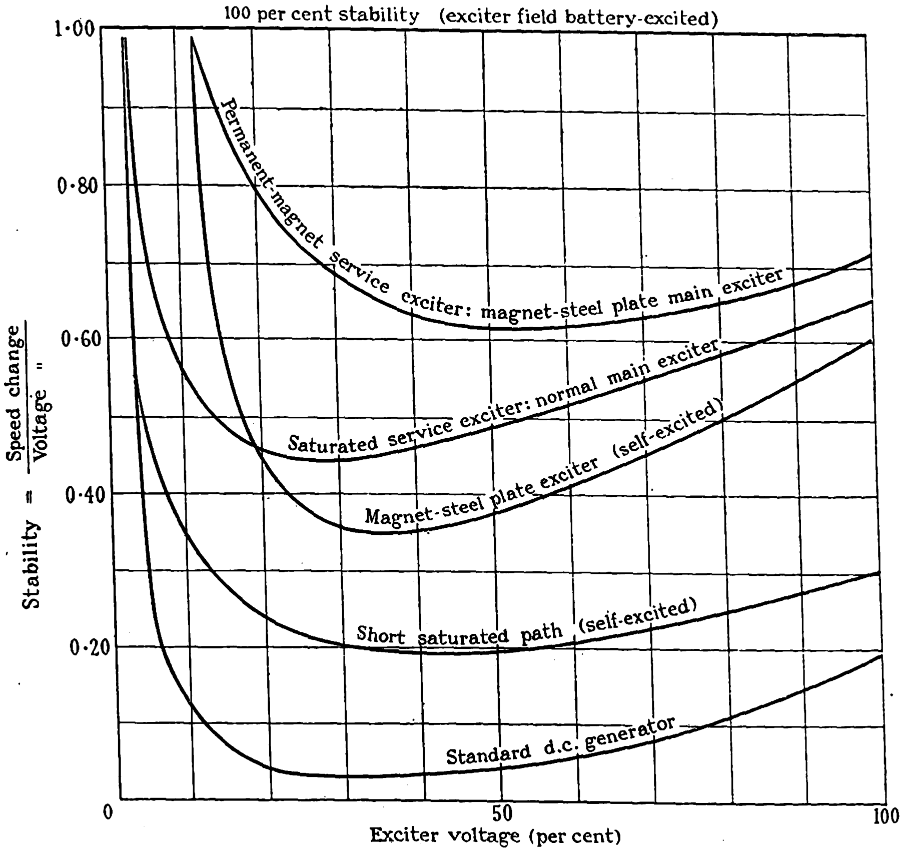

Fig. B.

Mr. J. D. Peattie: This paper is very welcome, coming as it does at a time when preparations are being made for linking up generating and distribution systems on a much larger scale than in the past. In this country the location of stations is close to the load centres, and our problems will differ from those which have arisen in other countries where heavy lines transmit power over long distances. On page 317 the author refers to the fact that magnet systems of larger machines require larger stores of electromagnetic energy, and therefore a longer time of response. I suggest that this statement requires amplification. It is not so much a matter of the actual amount of energy stored, as of the relation between that amount and the dimensions of the exciter, which is required to generate and maintain the energy in the magnet system. In considering transient phenomena such as those described by the author, it is of great assistance to keep in mind the energy aspect, rather than other quantities such as current and voltage which appear in intermediate calculations. Before it can be used to transmit energy from the turbine shafts to the ultimate consuming devices, any electrical system must be raised to a definite potential. I use " potential " in its original meaning as the amount of energy required to bring the system from rest to a given state. This energy is being drawn off continually at the consuming devices, and replenished by an equal flow at the turbine shafts. The energy content of a 3-phase system is in a state of continual circulation between the magnetic and electrostatic fields of the three phases. The exciter acts rather like a strut which helps to keep the system propped up to that potential. In the case referred to on page 323 of the paper, it may, if reverse excitation is used, act like a tension rod and keep the system down to the working potential. Any disturbance in the conditions immediately involves a redistribution of the internal stored energy. The rate of adjustment depends on the electrical dimensions of the system. The author's suggestions will be of assistance in determining the parts played by the alternator and exciter in such a readjustment, and in forming conclusions regarding the behaviour of the system as a whole. In the two main divisions of his argument, stability and response, the author deals with phenomena which occur, for example, in times greater than 1 sec., and between $\frac{1}{5}$ and 1 sec. I hope he will add a few remarks on voltage regulation within one cycle, that is in times less than $\frac{1}{50}$ sec. Alternators are specified to give sine waves of pressure on open circuit with a load of which the resistance, inductance and capacity are independent of voltage. In practice a considerable proportion of loads do not obey this simple rule, and a sine wave of pressure does not necessarily give a sine wave of current. It would be of great interest to know how much distortion can be introduced into the current wave of a modern alternator without distorting its voltage wave.

Mr. F. de la C. Chard : At the foot of page 318 the author states that: " The use of a cast-iron magnet frame in preference to one of steel helps the stability of a shunt machine." It seems to me that any means of producing initial saturation must have an adverse effect on the exciter response at higher exciter voltages, and more especially such a means as this of employing a material having the magnetic characteristics of cast iron. As there are other means of obtaining stability, which do not affect the response of the exciter, such as the method of inserting a material having high retentivity in the magnetic circuit, it would seem preferable to adopt them. The remarks of the author on the subject of old and present-day design, and the comparison of the two designs, are particularly interesting. He attributes the evolution of this design to two causes, one being the relative cheapness per unit of rating, and the other the mechanical considerations involved. I think that there is at least one other cause which should be included, namely, that of changed outlook. The perfection of the automatic voltage regulator has altered the relative value of alternator characteristics. Regulation figures, which were formerly kept as low as possible by minimizing the reactance of the alternator, are nowadays comparatively unimportant, while the large outputs that are usual to-day make a high figure for reactance essential as a means of protection in limiting the initial value of fault currents.

Mr. A. R. Everest: I think that one of the most interesting points brought out in the paper is the difference between the modern turbo-alternator and the machines of 25 years ago. Those who had occasion to deal with those early machines will remember that they were specified to have very close inherent regulation, and consequently only a small armature reaction was allowed in proportion to the field. It did not take very long to show that the design was entirely wrong for this class of machine. One was necessarily restricting the output for a given machine, and perhaps only rating the machines at a small fraction of their possible capacity. Moreover, there was the question of the behaviour of the machine under sudden short-circuits. Practice was gradually modified, and machines are now designed so as to have a much heavier armature reaction in proportion to field. As a result it has been possible for the size of machines to increase up to their present dimensions—for example, the 160 000-kW machine now in service in the United States. An output of 200 000 kW has been named as the probable upper limit of size according to present knowledge. A discussion has been taking place in France, recorded in the *Bulletin* of the Société Française des Ingénieurs Électriciens, on a subject very similar to that discussed by the author, namely, the question of the stability of the large turbo-alternator, and the method whereby it can best be excited. It appears that those who have taken part are divided into three groups: (1) Those who claim that on a short-circuit a machine should lose its flux very quickly, for the protection of apparatus generally; (2) those who claim that it should maintain its flux at full value; and (3) those who claim that the machine should maintain its flux, but that there should be a certain amount of flexibility, and associated with it a need for rapid recovery and therefore quick response of excitation. It is the last-named class who seem to have had the last word. The author has shown that with modern designs of turbo-alternators the exciter is required to operate with a stable voltage over a voltage range of about 4 to 1, and has indicated various constructional means which are alternatively employed to produce the required result. Of these, the method preferred by the author, namely, the provision of a separately energized exciter, appears worthy of general support.

[The author's reply to this discussion will be found on page 337.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 11TH NOVEMBER, 1929.

Mr. L. H. L. Badham: On page 323 the author considers alternator load stability with constant excitation on the basis that the alternator under discussion is the only machine supplying the load, but one machine generally constitutes a fraction of the total generator capacity supplying a network. Under these conditions the alternator, if left with a constant excitation, does not operate at the power factor of the increasing load but at constant voltage with an improved power factor, thus drawing excitation, by way of the stator windings, from the magnetizing power of the rest of the machines. In this way the limiting load which can be carried by the machine is increased, and it is interesting to determine what these limits are for a machine with the characteristics shown in Fig. 15. In Fig. C, excitation curves at normal voltage have been drawn for a range of power factors from zero (leading) to zero (lagging). For any given value of excitation the percentage rated current and corresponding power factor for each value of excitation chosen are shown in Fig. D. From these last curves it is observed that, with constant excitation, the load increases and the power factor improves up to a certain maximum kilowatt output. When this stage is passed, the alternator will fall out of step with the system. The curves show, however, that the machine has a considerable margin above the load for which excitation has been set. For instance, with excitation for 40 per cent load at rated power factor, the machine has a maximum capacity of about 10 per cent above its rated kilowatt load. The results are expressed in another way in Fig. E, in which the loads at which instability commences are plotted against the corresponding excitation. It is seen that the pull-out kW load occurs only after the power factor has become

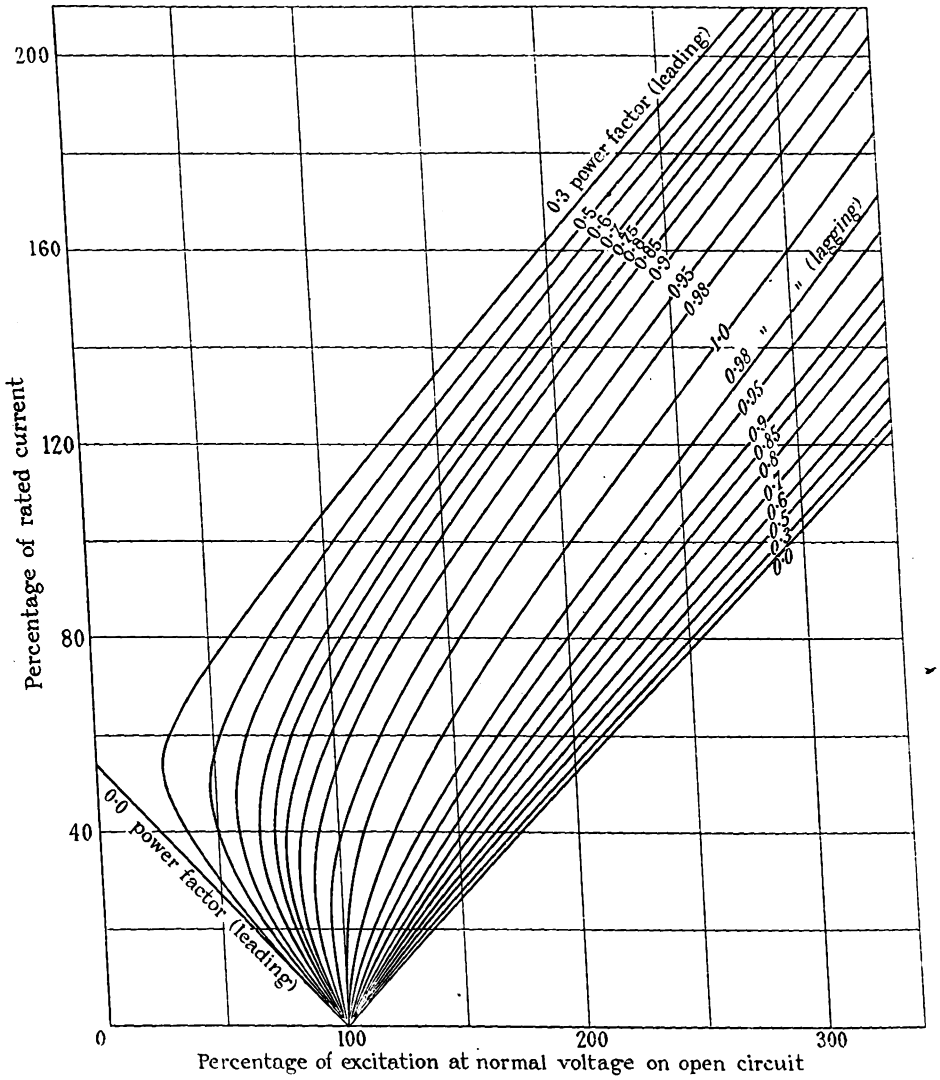

FIG. C.—Load excitation characteristics at normal voltage.

appreciably leading, and is directly proportional to the excitation. These results apply to steady condition of operation, but under momentary varying loads the maximum load which may be carried without falling out of step is greater than these owing to the effect of the armature transient on the field system, which augments the excitation and is a function of the time-constant of the alternator response (see that section of the paper which deals with alternator response alone).

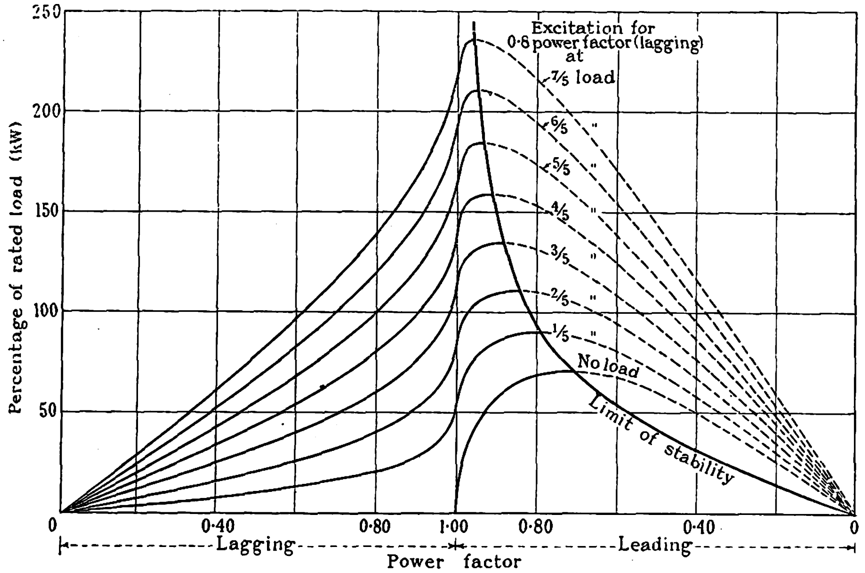

FIG. D.—Kilowatt/power-factor characteristics of alternator for various constant excitations when paralleled on a large system.

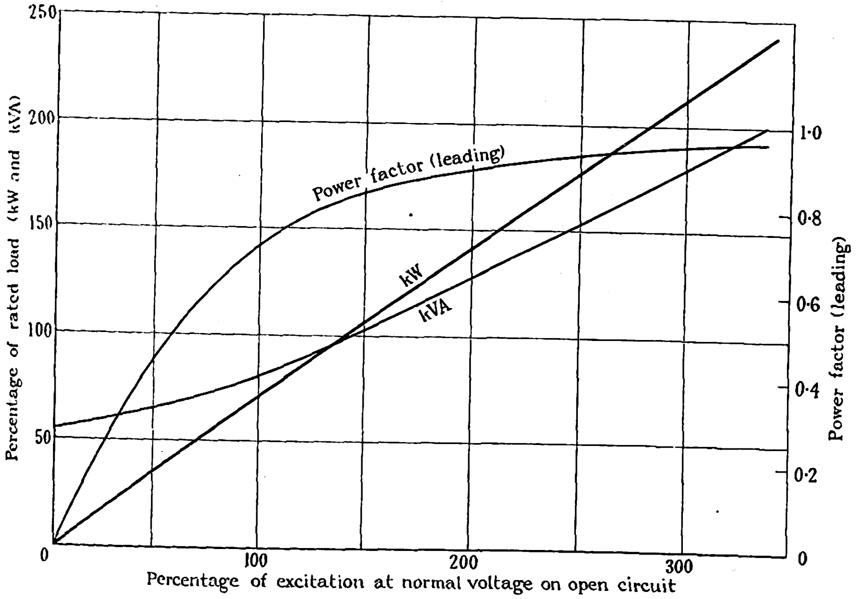

FIG. E.—Alternator characteristics at limit of stability when paralleled on large system at constant excitation.

Dr. R. G. Jakeman: It is well known that the separately-excited exciter for large turbo-alternators solves the problem of exciter instability, and the author's paper gives a very clear comparison of this type of excitation with the ordinary self-excited exciter. It does not appear, however, that the disadvantage of the properly designed self-excited exciter is very marked, especially in view of the fact that a very large number of such exciters are in satisfactory operation. The disadvantages of exciting the main exciter from a small direct-coupled machine are increased cost, increased length of set and the fact that there is another commutator to look after. The author states that to compound an exciter does not improve the load stability, but in my experience it does definitely do so. The series field compensates to a certain extent for the distortion caused by the armature reaction. I should like to ask what the author's experience is of the surge caused by slipping a pole. I understand that tests have been carried out on this point without any disturbance being detected. Finally, it is not quite clear to me what is the effect of the lack of equalizing connections on a lap winding.

Mr. F. C. Hall: It seems to me that in order to obtain a ready response in both the exciter and alternator field circuits a low time-constant in each of these circuits is most desirable, and as the resistance of the field coils is an important function of the time-constant it plays a big part in the satisfactory regulation obtainable. Curiously enough, the usual method of obtaining a ready response is to cut out or cut in external resistance in the exciter field circuit, the former to raise and the latter to lower the voltage. In the case of raising the voltage this action opposes the object to be achieved, because the more resistance there is in the exciter field circuit the lower will be the time-constant. If we refer to Fig. 6 the above arguments appear to be borne out by actual tests taken by the author. It will be seen that the time required to raise the voltage is appreciably greater than that required to lower it. Curves (b) illustrate this point best, and curves (a) show that the difficulty is largely overcome by means of separate excitation of the exciter fields. It seems that if some method of improved ventilation of the exciter field coils could be found to enable more heat to be dissipated in the coils, they might be made of wire of a higher resistance than copper so as to leave more internal resistance in the circuit when cutting out the external resistance by means of the regulator. This result can, of course, be achieved by retaining an equivalent amount of external resistance, and there would naturally be consequent losses in either case. If there are other difficulties I should be glad if the author would mention them in his reply.

Mr. G. R. J. Parkinson: Although the paper deals chiefly with the design of exciters and alternators, the author has thrown light on a number of phenomena which I have experienced as an operating engineer. I am particularly interested in Fig. 12. The company with which I am connected has had to deal with an industrial load, chiefly induction motors, at a very poor power factor, sometimes as low as 0·65 lagging. A number of static condensers have been connected, and although many are fixed in substations, and switched off as required, others, connected directly to consumers' transformers, are not switched off at week-ends and holidays, the result being that on Sunday mornings, and at times of very light load, the power factor of the system is about 0·4 leading. On these occasions, with one generator running, the voltage is extremely unstable, the smallest movement of the exciter rheostat causing the voltage to vary between 50 and 150 per cent of the normal. Steps have now been taken to see that these condensers are disconnected at times of very light load. The author refers to the necessity of maintaining full voltage in the event of a short-circuit on the system, and although I recognize the importance of maintaining an uninterrupted supply there are occasions when a serious drop in voltage is the lesser of two evils. Most supply engineers have found it extremely difficult to keep their switchgear quite up-to-date: their undertakings have grown so rapidly that the rupturing capacity of their switchgear has not kept pace with the growth of their generating plant, and in the event of a serious short-circuit a drop in voltage may prevent the burn-out of a switch panel and a complete shut-down. The author mentions the advisability of engineers operating their generators at the power factor for which the machines were designed. Although I can sympathize with him as a designer, I must point out the difficulties from an operating engineer's point of view. In a public supply the power factor varies tremendously at different times of the day and week, and I have found it advisable to order machines to give their full kilowatt output at the lowest power factor that is ever likely to be experienced. It may be that if such a machine be used generally at a higher power factor the instability and response may be somewhat worse, but on the other hand the high overload capacity on higher power factors may prove very useful. Referring to the reversal of an exciter, following a short-circuit on the alternator, I have found that this is more likely to occur when the exciter is provided with laminated pole-pieces, rather than in one with solid poles, and I should like to ask the author whether he can explain this difference.

Dr. M. L. Kahn (*communicated*): The paper is of particular importance at the present moment, as the problems arising in the voltage control of large alternators are so intimately connected with the question of system stability which is bound to come under consideration in connection with the grid scheme. On page 324 the author reminds us that in the United States large turbo-alternators have generally lower percentages of armature reaction than some machines which have been in successful operation for a number of years on large systems in this country. I am not sure that this experience can be relied upon in the future in this country, with the growth of the supply system approaching the conditions which are to be found in the United States, more especially in view of the conditions which the interconnection of supply systems will introduce. On the other hand, as the author points out in his following remarks, a large percentage of armature reaction is unavoidable if machines of large output are to be built for a speed of 3 000 r.p.m. It will, therefore, be necessary to find a safeguard which will ensure system stability on large power systems even though the percentage armature reaction of the turbo-alternator is high. The solution of these problems is a combination of extremely quick-acting voltage regulators in conjunction with quick-response exciters. The author has given actual data to compare the various systems of excitation which are possible from this point of view. A point in connection with quick response of the excitation which has not been specifically mentioned in the paper is the fact that, if the voltage of a system is allowed to drop, the motors connected to the system take more current and some may even fall out of step. This may increase the current to such an extent that the alternator voltage falls more quickly than the excitation can be raised, in the event of the voltage control not taking effect immediately. On the other hand, with quick-response regulators and exciters the drop in voltage can be stayed in time, so that the unstable condition just described will not arise and the voltage of the alternator can be brought back to its normal value. From this it is evident that for large turbo-alternators it is essential to adopt the system of excitation which gives the quickest response. From Figs. 21 and 24 it can be clearly seen that this is the system of an exciter which is separately excited and has, in addition, a very large voltage margin above the maximum voltage required for normal excitation. The additional expense involved by the adoption of this system will be well repaid by the increased stability of the power supply. An exciter possessing these features is shown in Fig. 4. I take it that this represents an exciter direct-coupled to a large turbo-alternator running at 1 500 r.p.m. For this speed the combination of two exciters on one shaft is quite practicable. On the other hand, for large turbo-alternators running at 3 000 r.p.m. such a combination would probably involve considerable mechanical difficulties and be less reliable than separately-driven exciters. Such exciters could, for example, be connected to condensing-plant pumps. In the development of the scheme for the calculation of response of the various field systems, the author frequently refers to a "time-constant." This expression is derived from the corresponding feature of a general circuit with a given reactance and resistance. Whilst for this general circuit this factor—the reactance divided by the resistance—is a constant, the factor becomes variable if used in the way the author applies it for exciters and turbo-alternators, and it is rather bewildering to find in Fig. 20 that this time-constant will vary so much for a given alternator. It would, therefore, be preferable to call this feature the "time-factor," especially as the variation with the load shown in Fig. 20 does not occur in the time-constant of the general circuit, from which the expression is taken. It is not quite clear from the paper why this time-factor is affected so much by the load, and a further explanation would be of great interest. The definition of the response figure given on page 320 is also somewhat difficult to understand on first reading it. Would it not be better to define the response figure as the voltage growth per second, or as the rate of voltage growth? That is what I understand the author to intend it to mean. For the straight part of the curves (a) and (b) in Fig. 6, the response is constant and can be read directly from these curves. I am particularly interested in Fig. 17, from which the voltage-drop of the alternator for constant impedance can be calculated for any load variation. In his figures for the voltage-drop on page 325 the author has given this drop for constant impedance, so far as I understand his meaning which is expressed in the words "when the full-load circuit is suddenly connected to the alternator terminals." It would be just as well if such a definition for the voltage-drop of an alternator were generally agreed upon, as the usual requirement in specifications, i.e. to state the voltage-drop if full load is switched on the alternator, is somewhat ambiguous. This is quite clear from the explanation of the conditions which arise when load is switched on to an alternator, and which are given at the top of page 324. Such expressions as "full-load circuit" or "full-load impedance" should always be introduced in specifying voltage-drops, so that one should say "if full-load impedance is switched on to the alternator," in preference to "if full load is switched on to the alternator." I cannot quite understand why the author states on page 323 that the time-factor of an exciter is not reduced if a large field conductor is used, or if the exciter field voltage is increased materially in case of separate excitation. Surely both alterations involve additional resistance in the exciter circuit with a corresponding reduction in the time-constant. Another point on which I cannot follow the author's reasoning is the effect of the series winding on the exciter with reference to reversal of polarity. An increase in series ampere-turns due to the sudden rise of current in the alternator field circuit can only affect the current in the shunt coils of the exciter in so far as it tends to change the flux. It is, therefore, essential to consider the sum of all the magnetomotive forces acting on the magnetic circuit, including the armature ampere-turns. If the series ampere-turns are correctly dimensioned so as to counterbalance the armature ampere-turns, an increase in current will affect the series ampere-turns and armature ampere-turns equally, so that no material change in the magnetomotive force takes place and the shunt cannot be affected. Compounding is, therefore, if properly applied, quite effective in preventing the demagnetization of the exciter in case of a sudden increase of field current due, for example, to a short-circuit on the alternator.

THE AUTHOR'S REPLY TO THE DISCUSSIONS AT LONDON AND BIRMINGHAM.

Mr. H. W. Taylor (*in reply*): Mr. Kuyser has suggested a definition for exciter stability which gives all types of exciters the same merit at the lowest voltage, and for this reason I would rather refer to Fig. 2 and define exciter stability as the rate of increase of voltage in regard to field-circuit resistance.

The mechanical analogies suggested by Mr. Peattie are very interesting. His reference to voltage regulation within one cycle refers not so much to operation with change of load but to alternator wave-form with continuous load. The larger the alternator the less likely is a bad wave-form of current to distort the wave-form of voltage.

I think Mr. de la Chard has taken our statement "The use of a cast-iron magnet frame in preference to one of steel helps the stability of the shunt machine" as a recommendation as regards policy for best stability and response. A general recommendation, however, is given on page 323 and is to the effect that the exciter should be separately excited and the poles and magnet frames laminated, and that no metallic support should be used for the field spools.

Mr. Everest has contributed some interesting notes on the development of the modern machine. With regard to the discussion between the French engineers, we agree with the middle course they seem to have adopted, namely, not to attempt to maintain the flux under extreme conditions but to provide for its rapid recovery as soon as normal conditions are restored.

Mr. Badham has taken the characteristics of a modern turbo-alternator as given in the paper and has developed some interesting curves showing that when this machine is allowed to trail it has a satisfactory margin of overload, provided the excitation is set at a reasonable value. In order, however, to have full advantage, in the case of faults, of all the excitation available on all machines, it is recommended that each machine should always be in operation with its own regulator.

Dr. Jakeman and other speakers have referred to the use of compound field windings on exciters and to the reversal of exciter voltage. The arguments for and against their use may be summarized as follows: As mentioned on page 319, series windings do not improve the inherent instability of a shunt machine; again, series windings do not improve the response because the time-constant of the exciter is inversely proportional to the total section of conductive material on the field spool; series windings do not have an immediate effect in overcoming load instability, because they act at right angles to the armature reaction and the latter is quicker in depressing the armature voltage than current on the field coils is in raising it; when, however, a shunt exciter is designed with a relatively short air-gap as an ordinary direct-current machine, exciter voltage oscillation and even reversal may occur with large changes in load on the alternator, and a small amount of series winding will prevent this; the same result, however, can be obtained without the series field winding if the air-gap is proportioned as indicated on page 317. With a separately-excited machine, reversal of voltage with changes in alternator load will not occur. The station voltage can remain undisturbed when, due to instability, one of the exciters reverses its voltage and its alternator slips a pole, if other machines running in parallel are controlled by regulators and excited with exciters which can, for the time being, supply the necessary extra excitation. All lap-wound exciter armatures should have equalizing connections. If these are not provided, there is a tendency at low voltage for an inequality in the poles to cause the machine to build up as a 2-pole machine, under which condition connections between brush arms which, for 4-pole operation, are of the same polarity, become short-circuiting connections between brushes of opposite polarity. This effect has been noticed even with the shunt exciter on open circuit and therefore without current round the commutating poles, but is not likely to occur with the air-gap proportions indicated on page 317.

In reply to Mr. Hall, it is not possible to cause the exciter voltage to rise as quickly as it can be made to fall in the same machine. His suggestion to improve the response of the machine by improved ventilation of the field coils is, in fact, the procedure which is adopted by the designers, but there is no advantage in using material other than copper on a field spool having a given heat-dissipating capacity. The use of an external resistance with correspondingly higher excitation voltage for the exciter would improve its time-constant, but its response could be still further increased by using the higher excitation voltage without the resistance.

Mr. Parkinson's experiences with the operation of machines over a wide range of power factor and the consequent instability at low power factors are of interest and there is no doubt that the stabilized exciter proposed in the paper is particularly useful under these conditions. Referring to Mr. Parkinson's experience that exciter voltage-reversal is more likely to occur with one provided with laminated pole-pieces than with one having solid pole-pieces, I think this is due to the fact that the latter machine would have a slightly longer time-constant and therefore would be slower in losing its voltage with a sudden excessive amount of armature reaction.

In reply to Dr. Kahn, the constant volt-ampere curves in Fig. 7 were intended to indicate the case of motors taking more current with falling voltage, and his conclusion, that under such conditions the machine would eventually lose its voltage when quick-response regulators are not in use, is given at the top of page 327. Fig. 4 shows the proportions of a machine actually used for exciting a 1 500-r.p.m. turbo-alternator, but similar machines with both exciters in the one frame are also in successful operation for large turbo-alternators running at 3 000 r.p.m. I agree that it is unfortunate and perhaps bewildering that the time-constants of both the exciters and the alternators vary with conditions of load. This arises from the fact that in the exciter we have saturation at higher voltages and in the alternator we have different circuits connected as load to the alternator terminals, so that the alternator flux per ampere of rotor excitation, upon which the time-constant depends, is less at high loads than at low loads. These difficulties are dealt with in the paper by defining the time-constant of the exciter and the alternator for the initial straight part of the saturation curves and with no external resistance, and then giving, in the case of the exciter, the response curves at different voltages as in Fig. 7, and, for the alternator, the time-constant at different loads as in Fig. 20. When the time-constant is defined in this way, the statement, that it does not vary for different excitation voltages or when a larger field conductor is used with correspondingly fewer number of turns, will be understood.

ALTERNATING-CURRENT POTENTIOMETERS AND THEIR APPLICATIONS.

By C. V. Drysdale, O.B.E., D.Sc., F.R.S.E., Member.

(*Paper first received* 29*th July, and in final form* 26*th September*, 1929; *read before the* Meter and Instrument Section 6*th December*, 1929.)

Summary.

An historical account of the evolution of the a.c. potentiometer is given, followed by descriptions of the Drysdale-Tinsley, Larsen, Gall, Pedersen, Campbell and other types of the instrument. The theory and accuracy of such instruments are discussed, and examples are given of their application for various tests.

(1) Introduction.

No department of electrical testing involves such difficulties and such costly equipment as that of accurate a.c. measurements. The great majority of alternating-current and p.d. measuring instruments have only a limited range, owing to the square law which underlies their operation, so that to cover the range from, say, a few milliamperes to several thousand amperes, and from a few millivolts to 100 kV, a formidable array of such instruments is required, which is still further increased when polyphase circuits have to be dealt with and wattmeters have to be provided for power and phase measurements. The battery of costly instruments for covering the above requirements within an accuracy of 1/10th of 1 per cent is beyond the resources of all but Government Departments and wealthy concerns: and a single instrument which can deal with the situation, even at the cost of some sacrifice of convenience and accuracy, is certainly the greatest need of the instrument maker and smaller standardizing laboratories.

The most universal of direct-current testing instruments is, of course, the potentiometer, which was first suggested in practical form by Sir Ambrose Fleming in 1885[*] and developed by Col. Crompton. In this form of instrument, which has persisted with only minor modifications to the present day, a number of equal-resistance coils (originally 14) and a slide wire having a resistance a little greater than that of one of the coils are connected in series. If each coil is of exactly 2 ohms resistance, and a current of 0·05 ampere is passed through the whole series, there will be a p.d. of 0·1 volt across each coil, and a total p.d. of a little over 1·5 volt across the coils and slide wire; and any p.d. up to this maximum can be tapped off between two sliding contacts on the studs and slide wire. The correct current is obtained by connecting the potentiometer through coarse and fine rheostats to a steady 2-volt secondary cell and balancing against the known e.m.f. of a standard cell.

The Crompton potentiometer is certainly the most simple and convenient of such instruments, but it suffers from the defect that p.d.'s of less than 0·1 volt can only be measured on the slide wire, which, unless it is extraordinarily uniform, limits the accuracy of measurement to an appreciable fraction of 1 per cent. The measurement of current by the potentiometer is effected by passing the current through a standard resistance or shunt and measuring the p.d. across it, and if the current is, say, 1 000 amperes this involves a power consumption of 100 watts for 0·1 volt, and a proportionately higher consumption for heavier currents. Unless the resistance standards are large and costly and provided with elaborate cooling arrangements, therefore, a drop of 0·1 volt is the maximum which can be allowed for heavy-current measurements, and the whole measurement must therefore be made on the slide wire. It is consequently desirable to relegate the slide wire to the next decimal place so that 9 coils are in series with it when measuring a p.d. of 0·1 volt, and this may be done in any one of three ways. The simplest of these is to employ a "transposition circuit" (Fig. 1) which consists of two coils, one having a resistance of 1/9th of that of the whole potentiometer circuit and the other a resistance 9/10ths of it. By turning a switch the potentiometer is shunted with the former coil, reducing its resistance to 1/10th, while the second coil is connected in series with the combination, restoring the total resistance and current to their former values. The current through the potentiometer, and hence the p.d. corresponding to its readings, are therefore reduced to exactly 1/10th of their normal values. This device has been fitted to the later types of Crompton potentiometer and is quite effective, the only objections to it being that the p.d. of the secondary cell supplying the constant current may be slightly disturbed by the process of switching over, and that for such a low-resistance instrument the shunt must also have a very low value and care must be taken to have a very perfect contact in the switch.

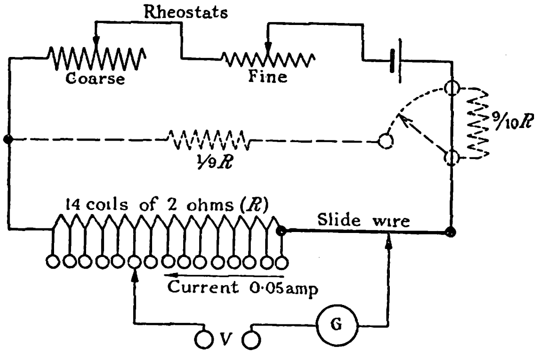

Fig. 1.—Crompton potentiometer—"Transposition circuit" shown dotted.

The remaining two methods consist in employing two resistance dials in series with the slide wire. In one of these (Fig. 2), which may be said to be on the Kelvin and Varley slide principle, the second dial of 10 equal coils has a total resistance equal to that of two coils of the first dial, and is connected across a double-contact switch spanning two studs of that dial so that the parallel resistance of the combination is exactly that of one coil, and the p.d. of 0·1 volt across it is subdivided to 0·01 volt. The slide-wire resistance is then reduced to 1/10th of its former value. Messrs. Tinsley's "universal potentiometer" is of this type. The third device employs the Feussner principle of replacement in which any number of dials can be connected in series, but the resistances are duplicated so that for any increase of resistance between the potential points an equal reduction is made in the resistance of the remainder of the circuit, so that the total resistance, and hence the current, remain constant. In the case of a 2-dial and slide-wire potentiometer only one of the dials need be thus duplicated, as indicated in Fig. 3.

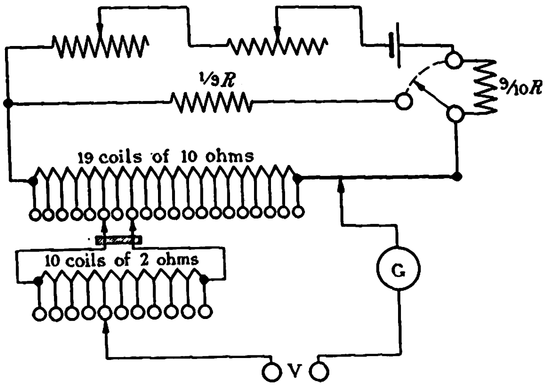

FIG. 2.—Two-dial and slide-wire potentiometer (Kelvin-Varley principle).

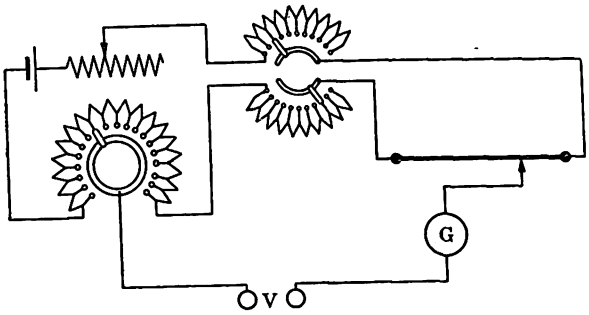

FIG. 3.—Two-dial and slide-wire potentiometer (Feussner).

Both of these double-dial potentiometers have the disadvantage, as compared with the simple Crompton form, of having sliding contacts in the resistance included between the potential leads, but if care is taken over these contacts little error is caused by them. The Kelvin-Varley principle has the advantage over the Feussner form of requiring fewer coils and of having twice the resistance in the second dial, so that contact errors have less effect. On the whole, therefore, it seems preferable; and the author, in his report on the electrical exhibits of the St. Louis exhibition of 1904, suggested this type as the most generally useful and has since adopted it for the a.c. potentiometer to be described in this paper.

Before leaving this section, it may be well to refer to the application of the d.c. potentiometer to p.d., current and resistance measurements, for comparison with a.c. potentiometer measurements later. Fig. 4 shows the standard connections for testing a d.c. load of any kind. The load is simply connected to the appropriate d.c. mains through a standard resistance R_s of suitable current-carrying capacity, and the p.d.'s V_1 and V_2 across the load and resistance are successively measured on the potentiometer, from which the current $I = V_2/R_s$ and the power absorbed by the load and "volt box" combined, $P = V_1 I = V_1 V_2 / R_s$. If V_1 is less than 1·8 volts it can be directly measured, but if it is higher a "volt box" or potential divider is connected across it as shown by the dotted lines, and a known fraction of the p.d. is measured. If the load is a simple resistance, its value is obviously $V_1 I = (V_1/V_2)\ R_s$ if no volt box is used, and a simple correction can be made for the shunting effect of the latter when employed. It will be seen below that a.c. potentiometer testing is conducted in precisely the same manner, and the same standard resistances and volt boxes can be employed for either d.c. or a.c. measurement, provided that they are sufficiently non-inductive.

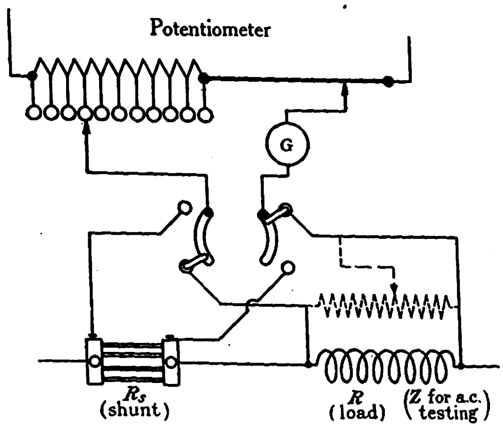

FIG. 4.—Current and p.d. measurement.

(2) EARLY ATTEMPTS AT A.C. POTENTIOMETERS.

The great range and accuracy of the d.c. potentiometer soon led to a desire for a similar instrument for a.c. testing, and various suggestions for what may be termed transference devices, enabling the alternating p.d. to be measured to be balanced against an equal continuous p.d. derived from the potentiometer, were made. One of the first and the most simple in principle was that suggested by Mr. J. Swinburne in 1894 * and consisted of interposing a sensitive quadrant electrometer between the potentiometer and a.c. circuit as in Fig. 5. This manner of connecting the electrometer makes it differential, and balance is obtained when the p.d. V_1 derived from the potentiometer is equal to the R.M.S. value of the alternating p.d. V'; so that all that

---

* See Reference (2).

has to be done to measure the latter is to use the electrometer in place of the ordinary galvanometer, and vary V_1 to secure balance. In principle this method is quite correct and it could be used quite well for p.d.'s of about, say, 20 volts and higher, but its application is limited by the extreme insensitiveness of electrometers at the low p.d.'s employed in current measurements; by the difficulty of obtaining exact symmetry in the electrometer; and by the Volta or "contact" e.m.f.'s between the needle and quadrant, which are very difficult to eliminate and which may be a material fraction of the p.d. under measurement. So far as the author is aware, there is no record of this method having been put into practice; and the first transference device to be actually used was probably the heated platinum tube employed by Orlich * at the Technische Hochschule at Charlottenburg for the measurement of large alternating currents. The alternating current to be measured was passed through a platinum tube (Fig. 6) of such section as to heat it to incandescence, and its temperature was then observed by an optical pyrometer of the disappearing-filament type, and reproduced by switching the platinum tube over to direct current, which was measured by the potentiometer. This device, when carefully used, was capable of measuring within an accuracy of a few tenths of 1 per cent, provided that the tubes were sufficiently long to give uniformity of temperature and to eliminate the action of Peltier effects, but the platinum tubes were very costly and took some time to attain a steady temperature, so that measurements were slow and the waste of energy was enormous. The author consequently modified it by using a shunted metal-filament lamp and matching it with a comparison lamp on a Lummer photometer. A further obvious simplification of this method is to connect a thin hot-wire element to the potential terminals of a suitable resistance or shunt and to determine the temperature of the wire by the ordinary cross thermo-junction. If two such elements (Fig. 7) are accurately paired, and their thermo-junctions connected in series and in opposition, they form a differential electrometer, though of course without the advantage of requiring no power for small p.d. measurements. The "thermo-convertors" recently introduced by Dr. Moll of Utrecht * would seem to be ideal for this purpose, as, owing to the large number of thermo-junctions employed, a temperature-rise in the heated wire of only a few degrees is amply sufficient, and they can be very accurately paired.

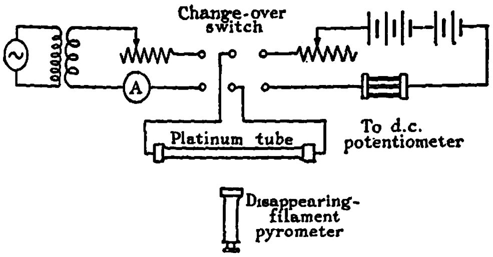

FIG. 6.—Orlich's platinum-tube method.

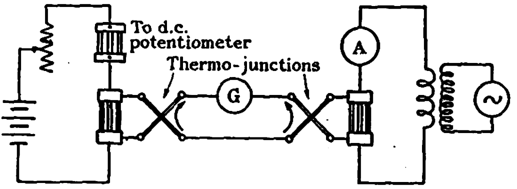

FIG. 7.—Thermo-junction method.

Franke Double Alternator.—As early as 1891 Herr A. Franke,† who had already done some valuable work on d.c. potentiometers, conceived the principle which is now used in all a.c. potentiometers, namely of balancing the alternating p.d. to be measured by a known alternating p.d. which can be varied both in magnitude and phase so as to reproduce the former exactly. His device (Fig. 8) consisted of two small alternators with a common revolving field magnet coupled to a driving motor, the armature G_1 being rotatable round its axis by a worm N_1 so as to alter the phase of its e.m.f. with respect to that of the armature G_2, which could be moved axially by a micrometer screw P_2 which moved it out of the magnetic field and thus enabled the magnitude of its e.m.f. to be continuously varied. The circuit to be tested was connected to the first alternator, and the two points between which the p.d. was to be measured were connected through a detector (usually a telephone receiver) to the second alternator, balance being obtained by rotating the first and sliding the second armature. The device can hardly be described as a potentiometer in the ordinary sense of the word, but it fulfils the same purpose, and it is of interest as being the first device in

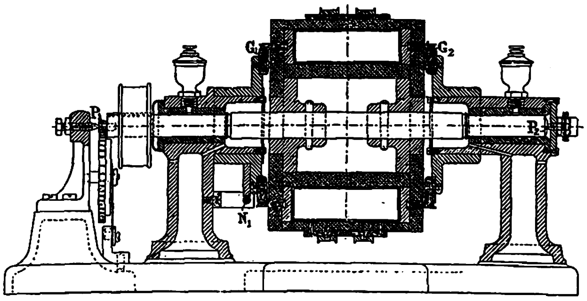

FIG. 8.—Franke double alternator.

† *Ibid.*, (5)

which the principle of balancing and measuring the phase as well as the magnitude of the p.d. to be measured was employed.

The double-alternator method has much to commend it, as there is no need for phase-splitting devices, and its accuracy of phase displacement is limited only by the accuracy to which the circular scale can be read. It is not, however, convenient for measurements involving large power, as the phase adjustment must be made at the machine itself.

In a later form * the Franke double alternator was enlarged and made with a vertical spindle, and the number of poles was increased to 40, giving frequencies up to 2 000 cycles per sec. with a moderate speed of rotation; but the variation of magnitude by axial displacement of one of the armatures was retained. It seems curious that this should not have been replaced by a potentiometer across the rotatable armature, as a potentiometer device was most probably employed for calibration. The machine was made by Messrs. Siemens and Halske and has proved of great value in telephone and cable investigations.

(3) Modern A.C. Potentiometers.

Drysdale A.C.–D.C. Potentiometer.—Unfortunately the Franke device was little known in this country, and in 1908 the present author, after devising some phase-shifting transformers for facilitating wattmeter and supply-meter testing, independently conceived the principle of considering the alternating p.d. as a vector and balancing it both in magnitude and in phase by a similar p.d. derived from a potentiometer fed with alternating current from such a phase-shifting transformer.† This immediately solved the problem of sensitivity, as it was quite easy to balance within a few microvolts by the aid of a sensitive vibration galvanometer, and it eliminated all transference devices and permitted a.c. measurements to be made with the same " shunts " and volt boxes as those used for d.c. measurements, provided that the former were sufficiently non-inductive. On the other hand, this method was only theoretically accurate for measurements on fairly closely sinusoidal supplies, but a moderate departure from pure sine wave-form involved only a relatively small error, which could be neglected or eliminated in many cases. Modern wave-forms are generally so closely sinusoidal that the errors are inappreciable, except when distortion is introduced by iron-cored inductances.

One advantage of this method, in which both the potentiometer and test circuit are supplied from the same a.c. mains, over the Franke method, is that in the former method the relation between the p.d. in the mains to the potentiometer current is constant, and a single initial reading of this p.d. is sufficient; whereas in the double-alternator method any variation of the load on the supply alternator causes a change of the magnitude and phase of its p.d. and therefore necessitates two readings for each load.

Fig. 9 shows the elementary scheme of such a potentiometer. It consists essentially of an ordinary potentiometer, say of the 2-dial and slide-wire type, with two regulating rheostats. A dynamometer ammeter D, with a fiducial mark corresponding to a current of 50 mA, is connected in series with the coils, and the secondary of a phase-shifting transformer is substituted for the ordinary accumulator. The primary of this transformer has a 2-phase winding, both phases being connected to the supply mains, one directly and the other through a resistance and condenser for splitting the phase and giving the necessary quadrature supply, the correct phase-splitting being obtained by adjusting the capacity and resistance until the dynamometer deflection remains constant when the secondary is rotated. When this condition is secured, turning the secondary through any angle changes the phase of the current in the potentiometer coils, and therefore the p.d. across any section of them, by the same angle.

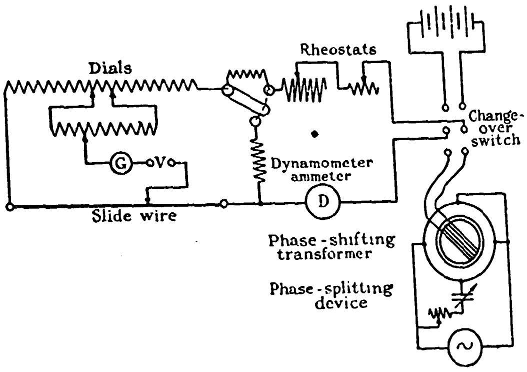

FIG. 9.—Elementary diagram of Drysdale potentiometer.

The two sliding contacts of the potentiometer are connected in the ordinary way to a selector switch through a galvanometer, which in this case is a sensitive vibration galvanometer tuned to the supply frequency.

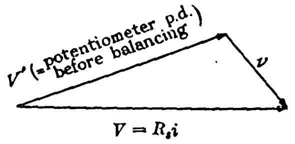

FIG. 10.—Vector diagram of Drysdale potentiometer.

The circuit to be tested, having an effective impedance Z, is connected in series with a known non-inductive resistance R_s to the secondary of a transformer fed from the mains, and R_s and Z are connected to the contacts of the selector switch exactly as for testing d.c. loads (Fig. 4). The current through the combination produces across the shunt (Fig. 10) a p.d. $V = R_s i$ which is in phase with the current, while the p.d. V' between the potentiometer contacts prior to securing balance will generally differ from it both in magnitude and phase, giving a vector difference v which deflects the vibration galvanometer. By successively rotating the phase shifter and adjusting the potentiometer contacts, the galvanometer can be brought to balance, in which case the p.d. between the potentiometer contacts is identical both in magnitude and in phase with the voltage-drop over the resistance, and their values can be read off from the potentiometer and the phase-shifter scales. If the load Z is due to an ammeter it can be calibrated in this way, but if it is an impedance of any kind its value is obtained by turning the selector switch and balancing the p.d. V' across it as before. Then V' is given as a vector the lag or lead of which (ϕ) with respect to $R_s i$ or to i is given by the angle turned through by the phase shifter, from which the impedance $Z = R_s(V'/V)\underline{/\phi}$ and the effective resistance and reactance of the coil are $Z \cos \phi$ and $Z \sin \phi$ respectively. By the aid of a cosine scale on the transformer and two pointers at right angles, $\cos \phi$ and $\sin \phi$ can be directly read off.

---

* See Reference (6). † *Ibid.*, (7).

Alternating-current measurements on sinusoidal waveforms may, in fact, be considered as vector surveying or triangulation, and this type of potentiometer is an electrical vector-surveying instrument in which the measuring tape or chain is represented by the dials and slide wire, and the prismatic compass, sextant or theodolite by the phase-shifting transformer.

The detailed description and applications of the instrument will be reserved until later, but one further matter of principle may be referred to here. In standardizing work the d.c. potentiometer is referred to a standard cell, and it is desirable that this feature should be retained in a.c. testing, instead of relying on the dynamometer. This is easily effected in the a.c. potentiometer by providing it with a changeover switch which replaces the secondary of the phase shifter by a 4-cell accumulator (the extra 6 volts being required on account of the resistance of the dynamometer), and the vibration galvanometer by an ordinary moving-coil galvanometer. When this switch is thrown over, the potentiometer becomes an ordinary d.c. instrument, and a standard cell can be balanced in the usual manner. In this case the dynamometer should indicate the standard current of 50 mA in the coils, but if not it can be adjusted to this reading by the ordinary zero adjustment, after which all alternating-current p.d.'s are measured in terms of the standard cell. The instrument is, of course, equally available as an ordinary potentiometer for all d.c. measurements.

Before going into further details of this instrument, reference will now be made to other forms of a.c. potentiometer which have since been devised. It should be pointed out that, as there are two ways of defining a vector, there are two different principles upon which a.c. potentiometers may be based. A vector may be defined either in polar co-ordinates by its magnitude and angle (or $r\underline{/\theta}$), or in rectangular or Cartesian coordinates x and y, the well-known relations between these systems being

$$x = r\cos\theta, \quad \text{and} \quad y = r\sin\theta$$

or

$$r = \sqrt{(x^2+y^2)}, \quad \text{and} \quad \theta = \text{arc tan}\,(y/x)$$

The instrument above described is obviously a polar potentiometer, as it gives the magnitude and phase angle or $r\underline{/\theta}$ directly. For the great majority of purposes this is the most accurate and convenient principle, as if a p.d. or current is to be measured in calibrating an instrument it is much better to read it directly from the potentiometer dials than to measure the two components and calculate their resultant. It was for this reason that the author selected the polar principle in the first instance, and he still considers it to be the best all-round principle, although the rectangular principle has advantages in a limited number of cases.

Kennelly's Demonstration A.C. Potentiometer.—In 1911 Prof. A. E. Kennelly [*] of Harvard devised an instrument consisting of a large square of thin manganin sheet, across which two equal currents in quadrature were passed in rectangular directions (Fig. 11). The sheet was therefore a surface of rotating p.d., and if contact was made on it at any two points the magnitude of the p.d. between them was proportional to their distance apart, and its phase depended on the inclination of the line joining them. By fixing one contact at the centre of the plate, the other contact could be so moved as to balance any required p.d., whereupon the p.d. was immediately exhibited as a vector. Obviously such a device is not adapted for accurate measurements, but it forms a sort of a.c. vector blackboard and is admirably suited for teaching purposes.

Author's Demonstration Potentiometer.—In view of the great value of the a.c. potentiometer for teaching alternating-current theory, a simple form of the author's potentiometer has been made up on a vertical blackboard about 4 ft. square, having a small phase-shifting transformer at its centre. A light arm carrying a slide wire is attached to the phase-shifter spindle, and a sliding block like a slide-rule cursor carries a contact and a point for marking its position on the blackboard, which is marked off both in squares and in circles for reading either in rectangular or polar co-ordinates. A vibration galvanometer can be used for ordinary supply frequencies, but for frequencies of 200 cycles per sec. or higher an amplifier and loud-speaker form a very effective detector.

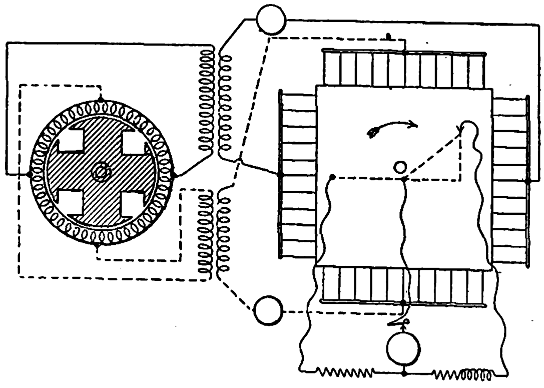

FIG. 11.—Kennelly's demonstration potentiometer.

Sharp and Crawford Potentiometer.—A simple form of polar potentiometer was devised by Messrs. Sharp and Crawford in the United States in 1910.[†] If a resistance with sliding potentiometer contact is connected across two of the terminals of a 3-phase supply, and the potentiometer is connected between this contact and the third terminal of the supply, the phase of the p.d. applied to the potentiometer can be varied over an angle of 60° by sliding the contact from one end to the other, but its magnitude varies from V to $\frac{1}{2}\sqrt{3}V$ between the end and centre positions. By employing two auto-transformers mechanically coupled through linkwork, this variation was eliminated, but the shift of phase could only be increased beyond 60° by changing the connections to the supply.

---

[†] *Ibid.*, (9).

Larsen Rectangular Potentiometer.—Turning now to the rectangular or Cartesian principle, it is easy to devise on it an accurate potentiometer for a definite known frequency. The most simple method, which was first definitely used for a potentiometer by Prof. A. Larsen of Copenhagen in 1910,* although its fundamental principle had already been conceived and utilized by Mr. A. Campbell in 1908,† is shown in Fig. 12, in which the ordinary resistance coils and slide wire are connected in series with the primary of a variable mutual inductance the secondary of which is joined in series with one of the sliding contacts. If i_1 is the potentiometer current, and R the resistance between the contacts, the p.d. between them will be Ri_1 in phase with the current, while the e.m.f. in the secondary of the mutual inductance M will be $M\omega i_1\underline{/90^\circ}$, where $\omega = 2\pi \times$ frequency. The p.d. v_2 of the combination will therefore be $(R + M\omega\underline{/90^\circ})i_1$ and the dial of the mutual inductance can be graduated directly in volts for a given frequency, so that the potentiometer reads the two components directly when any given p.d. is balanced. It will be seen, however, that, although the total magnitude can be obtained by calculation, the accuracy cannot be high unless the frequency is absolutely at its standard value, whereas in the polar potentiometer, although variations in frequency affect the phase-splitting and consequently the accuracy of the phase measurement, they do not cause any error in the magnitude if care is taken to see that the dynamometer current is correct or to adjust it when the balance is made. Prof. Larsen appears to have made up a complete potentiometer with a circular central-zero slide-wire and a variable mutual-inductance standard of the Campbell type, but with the primary and secondary systems doubled so as to give a central zero and symmetrical scale.

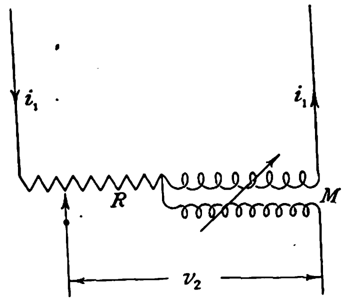

FIG. 12.—Larsen potentiometer—elementary diagram.

Hanson-Kennelly-Velander Potentiometer.—A self-contained potentiometer on the Larsen principle was devised and made at the Massachusetts Institute of Technology in 1919,‡ following a suggestion by Mr. Hanson in an MS. thesis in 1916. The instrument consisted of a 2-dial and slide-wire potentiometer of the Feussner type, and a mutual inductance made up of a number of elements arranged toroidally so as to give as small an external field as possible, the secondary coils being successively thrown into circuit by dial switches. A single small additional secondary coil was arranged to turn in the field of the toroid so as to give continuous variation over a small range, corresponding to the slide wire of the in-phase potentiometer.

Geyger's Potentiometer.—In order to avoid the use of a variable mutual inductance in the Larsen potentiometer, W. Geyger conceived the idea of employing a fixed mutual inductance the secondary of which was connected across a second potentiometer.* This of course involves loading the secondary and destroys the perfect quadrature relation, but Geyger claims that this error can be reduced to from 0·1 to 5 minutes of phase angle, which can be neglected, or allowed for in special cases. His first instrument (1924) was devised for demonstration purposes and had two slide wires along the two adjacent edges of a board, the sliders being provided with long arms the intersection of which showed the p.d. measured as a vector. He has since developed the device into a more accurate measuring instrument, which has been commercially manufactured by Messrs. Hartmann and Braun.

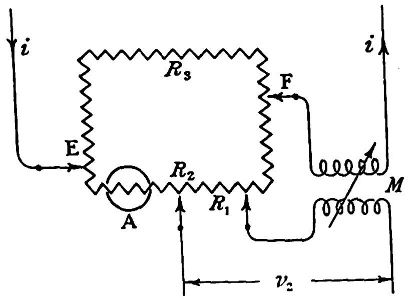

FIG. 13.—Larsen potentiometer—Campbell's loop shunt.

The Larsen principle has also been utilized by C. Déguisne,† who has also developed a method initiated by Schering and Alberti,† of the Reichsanstalt, for measuring the ratio and phase displacement in current transformers; it employs a shunted condenser in series with the potentiometer to shift the phase of its p.d. through small known angles. A special potentiometer method for testing potential transformers has been described by P. G. Agnew and T. T. Fitch,§ of the Bureau of Standards.

Campbell Direct-reading Potentiometer.—The great inconvenience of the Larsen device is the frequency factor in the quadrature component, which prevents the potentiometer from being made direct-reading except for one frequency. Mr. Campbell has, however, recently returned to the subject and has devised a practical form of potentiometer on these lines, in which the troublesome frequency factor in the quadrature component has been eliminated by an elegant application of the well-known Ayrton-Mather shunt.|| In the simple Larsen arrangement in which the same current flows through the resistance and the primary of the mutual inductance, the p.d. across the resistance is Ri_1, and the e.m.f. across the secondary of the mutual inductance is $jM\omega i_1$, so that for a given value of M the e.m.f. is proportional to the frequency. If, however, we arrange that the current through the primary of the mutual inductance is inversely proportional to the frequency, the product ωi_1 is constant and the e.m.f. is proportional to M only. Fig. 13 shows the scheme of the Campbell potentiometer in which the potentiometer resistance R_1 is in series with a non-inductive current indicator A and with a resistance forming a complete loop. The exciting current i is led in at a sliding contact E and divides into two portions flowing through the upper and lower sides of the loop, after which it unites at the sliding contact F and passes through the primary of the mutual inductance M. Then if i_1 is the current through A and R_1, and R_3 and R_2 are the resistances of the upper and lower portions of the loop between the contacts E and F, $(R_2 + R_3)$ is constant for all positions of the sliders and $i = i_1(R_2 + R_3)/R_3$.

---

* See Reference (10). † *Ibid.*, (11). ‡ *Ibid.*, (12).

* See Reference (13). † *Ibid.*, (14). ‡ *Ibid.*, (15). § *Ibid.*, (16). || *Ibid.*, (17).

Hence the p.d.

$$v_2 = R_1 i_1 + j\omega M i = \left(R_1 + j\frac{R_2 + R_3}{R_3} M\omega\right) i_1,$$

If we adjust R_3 in proportion to ω so that

$$R_3 = \left\{(R_2 + R_3)/b\right\}\omega, \text{ then } v_2 = (R_1 + jbM)i_1,$$

which is independent of the frequency. For example, if we wish to have a potentiometer in which the current i_1 is 0·01 amp. (100 ohms per volt) and the value of R_3 in ohms is equal to the number representing the frequency, $\left\{(R_2 + R_3)/R_3\right\}M\omega = 2\pi(R_2 + R_3)M = 100$ for $i_1 = 1$ amp.

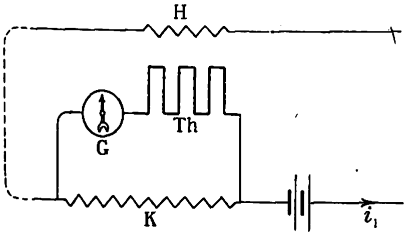

FIG. 14.—Campbell-Larsen potentiometer—thermopile device.

Hence the whole resistance of the loop $(R_2 + R_3) = 100/(2\pi M)$, and if we make $M = 10$ mH $= 0{\cdot}01$ H, $(R_2 + R_3) = 1\,592$ ohms. Then for 25 cycles per sec.

$$R_3 = 25,\ R_2 = 1\,567 \text{ ohms},\ i = 0{\cdot}637 \text{ amp.}$$

and for 1 000 cycles per sec.

$$R_3 = 1\,000,\ R_2 = 592 \text{ ohms},\ i = 0{\cdot}0159 \text{ amp.}$$

If the maximum p.d. across the potentiometer is to be 2 volts, the resistance of the potentiometer coils will be 200 ohms. It is not suggested that these are the actual resistances, etc., in the potentiometer as made, but the calculation illustrates the application of the principle.

An interesting feature of Mr. Campbell's potentiometer is the method he employs for keeping the current i_1 at its correct value. A thermopile Th (Fig. 14) is connected through a galvanometer G to the terminals of a low resistance K through which an auxiliary direct current is passed. A heater H is mounted close to the thermopile, and is at first connected in series with K. On passing the current, the galvanometer circuit has the p.d. across K in series with the e.m.f. of the thermopile, and if these are in opposition there will be some value of the current at which there will be balance, since the p.d. is proportional to the current and the e.m.f. to its square. By varying K this balance can be obtained for the required value i_1 of the current, after which a key is thrown over, disconnecting K from H but putting it in series with an equivalent resistance so that the current remains unchanged. If then an alternating current of strength i is passed through the heater H, balance will be restored. The heater is included in the potentiometer at A and enables the current to be adjusted during use.

The general appearance of the potentiometer is shown in Fig. 27, from which it will be seen that the resistance section and adjusting rheostats and heater are in one case, and the variable inductometer, giving the quadrature component, in a second case on the right. Readings of either component can be taken from about 10 μV up to 1·8 volts in phase or 1 volt in quadrature, and either component can be reversed by a switch so as to obtain readings in any quadrant.

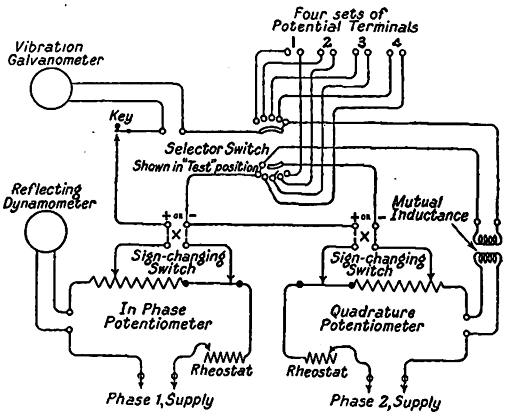

FIG. 15.—Gall co-ordinate potentiometer.

Gall Co-ordinate Potentiometer.—The first commercial potentiometer on the rectangular principle was, however, introduced by Mr. D. C. Gall in 1923 * and was on different lines from the above. Two exactly similar potentiometers (Fig. 15) are fed with equal currents in quadrature, and their sliding contacts are connected in series, so that their combined p.d. $V = V_1 + jV_2$, where V_1 and V_2 are the readings of the two potentiometers. By introducing reversing switches into the two instruments, either V_1 or V_2 can be reversed in sign or phase, allowing p.d.'s in any quadrant to be balanced. The two quadrature currents can, of course, be derived from a 2-phase alternator, but Mr. Gall adopted a phase-splitting device which is similar in effect to the resistance-condenser combination employed in the author's potentiometer, but substitutes a transformer or an ironclad mutual inductance for the condenser. In order to be able to ascertain whether the quadrature relation of the potentiometer currents is exactly correct, one of the circuits has the primary of a mutual inductance in series with it, the value of which is such that the secondary develops 0·5 volt with the normal primary current at 50 cycles, 0·6 volt at 60 cycles, and so on. Since this e.m.f. is in quadrature with the current in the primary, it must be in phase with the p.d. derived from the other potentiometer when the phase relation is correct, so that if the instrument is to be used on a 50-cycle supply all that is necessary is to set the in-phase potentiometer contacts to 0·5 volt and adjust the resistances of the phase-splitting device and those in series with the potentiometer until exact balance is obtained against the secondary of the mutual inductance; the correctness of this adjustment can be easily checked at any time during the tests. This test ensures the equality of the currents and the correct quadrature relation between them, while the correct value of the current is obtained by balancing a standard cell on the first potentiometer in the ordinary way. An external reflecting dynamometer is employed. The connections and vector diagram of the phase-splitting circuits are shown in Figs. 16 and 17, in which the vectors A, B, C and D on the vector diagram represent the p.d.'s across the correspondingly lettered component of the circuits.

---

* See Reference (18).

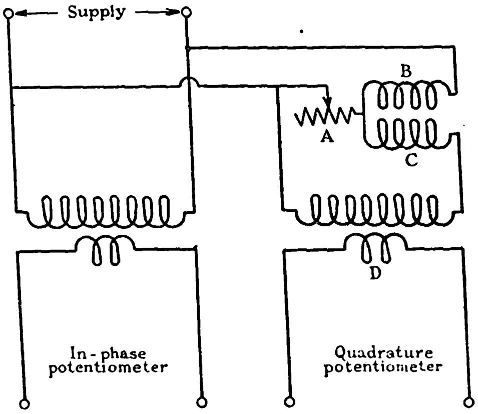

FIG. 16.—Gall potentiometer—phase-splitting device.

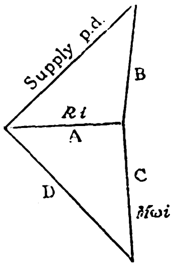

FIG. 17.—Gall potentiometer—vector diagram of phase-splitting device.

Recently Mr. Gall has introduced a simplified or portable self-contained a.c. potentiometer* on the same principle. It was primarily developed for testing the relay circuits in railway signalling work, and contains the vibration galvanometer, lamp and scale, shunts and volt box, so that no accessory apparatus is needed. In this case the quadrature current is obtained by condensers having fixed values for frequencies of 25, 33, 50, 75 and 100 cycles per sec., such condensers being plugged in at the left-hand side of the instrument. The diagram of connections is shown in Fig. 18 and is self-explanatory. The instrument is only intended for approximate commercial tests, and single slide-wire potentiometers only are employed.

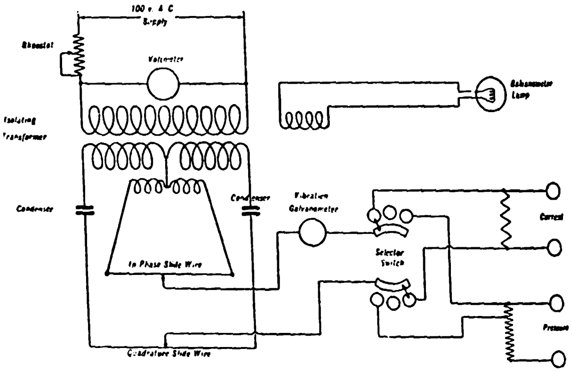

FIG. 18.—Gall portable a.c. potentiometer.

Pedersen Potentiometer.—The latest in principle and one of the most simple of a.c. potentiometers is that devised by Dr. O. Pedersen in 1919.* It is on the rectangular co-ordinate principle, and has the advantage, in common with the Larsen instrument, of maintaining its quadrature relation independently of the frequency, although this advantage is offset by the disadvantage that its p.d. indications in both phases vary with the frequency.

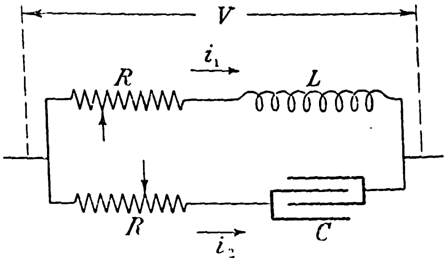

FIG. 19.—Pedersen potentiometer.

In Fig. 19 there are two circuits in parallel, each consisting of a potentiometer in series with an inductance L and capacity C respectively, the total resistance of each circuit being the same and equal to R. Then if V is the p.d. across the combination, the current in the inductive branch

$$i_1 = \left\{V/\sqrt{(R^2 + L^2\omega^2)}\right\}\overline{\backslash\phi_1}$$

while that in the condenser branch

$$i_2 = V/\sqrt{\left[R^2+\left\{1/(C^2\omega^2)\right\}\right]}\,\underline{/\phi_2}$$

where $\tan\phi_1 = L\omega/R$, and $\cot\phi_2 = CR\omega$

---

* See Reference (19).

* See Reference (20).

If $\tan \phi_1 = \cot \phi_2$ or $L\omega/R = CR\omega$, i_1 and i_2 will be in quadrature, so that if L is made equal to CR^2 this will be the case for all frequencies. Since the two resistances R have a common point, the p.d. between two potential contacts sliding on them can have components of any magnitude of either component up to the maximum, its value as a vector being represented, in the case where the two currents are equal, by the length and inclination of the line joining the contacts in the figure. As the frequency is increased, however, i_1 decreases and lags more, and i_2 increases and leads less, so that the values of the readings and their phase relation to the supply p.d. vary. The device can, however, be made direct-reading for a standard frequency, and it has recently been put into practical form by Messrs. H. Tinsley and Co.

In practice Dr. Pedersen extends the application of his principle by connecting the two slide-wire potentiometers between two equal inductances and two equal capacities respectively, as in Fig. 20, thus enabling both positive and negative values of the two component p.d.'s to be obtained. This device is used in the commercial form of the potentiometer. The instrument seems to have considerable utility for the measurement of impedances, as the frequency affects the potentiometer and the impedance tested similarly, but it is hardly suited for the direct measurement of p.d.'s unless it is designed for and used with one constant frequency.

A device resembling the Pedersen potentiometer, but using resistances instead of condensers, was described by Mr. A. K. Erlang of the Copenhagen Telephone Co. in 1913.* Two long slide-wires each of about 50 ohms resistance were connected exactly as in the later form of Pedersen potentiometer (Fig. 20), with two equal resistances at the two ends of one slide-wire and two equal inductances at the ends of the other wire. There is therefore a uniform p.d. gradient along each wire, but instead of these gradients being in quadrature they have a phase displacement of some smaller and known value, and the arrangement was found useful for telephonic measurements.

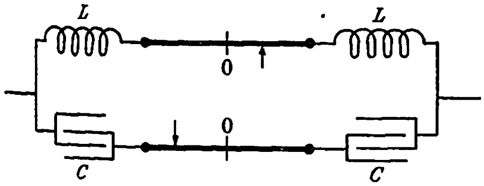

Fig. 20.—Pedersen potentiometer—double form.

B. S. and F. D. Smith's High-frequency Potentiometer.—The a.c. potentiometer principle is also applicable for high-frequency measurements up to radio frequencies, and a valuable start in this direction has been made by Messrs. B. S. and F. D. Smith at the Admiralty Research Laboratory † (see Fig. 21). It is on the polar principle, and follows the lines of the author's instrument in having a phase-shifting transformer which, in this case, consists of two pairs of coils at right angles, each pair being arranged like the coils of a Helmholtz tangent galvanometer in order to produce the most uniform magnetic field possible near their common centre. The high-frequency supply may be obtained from a valve oscillator, and the rotating field is secured by phase-splitting by resistance and capacity, as in the author's instrument.

The secondary coil is mounted on a vertical spindle, and the phase of the e.m.f. induced in it varies with turning in the ordinary manner, but instead of being connected to a potentiometer it is arranged to tilt as well as turn, so that the e.m.f. varies, approximately proportionally to the sine of the angle of the tilt, from zero when the plane of the coil is horizontal to a maximum when it is vertical. Any p.d. up to this maximum derived from the same supply can therefore be balanced by connecting the secondary directly to it through a detector and turning and tilting the coil, when the phase angle can be read off directly from a dial on the vertical spindle, and the magnitude from a scale on the micrometer head which tilts the coil by tension on the leads against an antagonistic spring on its horizontal spindle. The magnitude scale is approximately linear, and the most convenient method of calibrating it is to tilt the coil to approximately its vertical position and to adjust the supply and phase-splitting devices so that it gives about 1·5 volts on a Moullin voltmeter, constant for all orientations of the coil. Detection is most conveniently carried out by telephone and a heterodyne as in ordinary radio measurements.

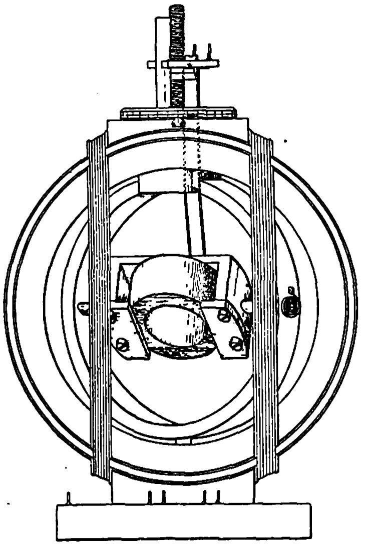

Fig. 21.—B. S. and F. D. Smith's potentiometer.

A device on somewhat similar lines to the above was described by K. Lion of Darmstadt in 1928.* It has two fixed coils at right angles which produce a rotating field by split-phase current, but these coils are of rectangular form, allowing of two secondary coils side by side, each of which can be independently turned round the axis, so that the phase difference between the e.m.f.'s induced in them is equal to the angle between their planes. One of these coils is used to supply current to the circuit under test, while the other is connected to a potentiometer. It is not easy to see what advantage is gained by the use of two secondary coils, and the arrangement seems seriously to limit the power available for the tests. It appears, however, to have proved useful for the testing of valves and amplifiers.

† *Ibid.*, (22).

* See Reference (23).

Wente Valve Potentiometer.—An ingenious a.c. potentiometer on the polar principle for frequencies up to 10 000 cycles per sec. has been devised by Mr. E. C. Wente of the Research Laboratories of the American Telephone Co. and Western Electric Co.* The diagram is shown in Fig. 22. The exciting supply from an alternator or valve oscillator is brought into the shielded transformer T_1, the secondary of which is connected across a condenser C and resistance R_c in series, thus giving two p.d.'s approximately in quadrature. These p.d.'s are communicated through a common grid-bias battery to the grids of two valves V_1 and V_2 the plates of which are connected through high resistances to the H.T. battery and earth, and also through condensers C_1 and C_2 to two transformers T_2 and T_3, the secondaries of which are connected through reversing switches to two resistances R_1 and R_2 having sliding contacts K_1 and K_2. These resistances are graded between their contact studs according to a sine law, and the p.d.'s across them are adjusted to equality by the help of a differential a.c. galvanometer so that if the contacts are coupled and moved together the p.d. between them is proportional to $v_1 \cos\theta - v_2 \sin\theta$, where $\theta = \frac{1}{2}\pi x/l$, x being the displacement of the sliders and l the length of the resistances. But $v_1 = v \cos \omega t$ and $v_2 = v \sin \omega t$, so that the p.d. between the contacts K_1 and K_2 is $v(\cos \omega t \cos\theta - \sin \omega t \sin\theta) = v \cos(\omega t + \theta)$, the phase of the p.d. thus varying continuously from zero to quadrature as the slider is moved, and by throwing over the reversing switches the whole of the 360 degrees can be covered. The p.d. from the sliders is communicated to the grid of a third valve V_3 which supplies a transformer T_4 connected across the potentiometer R. The whole of the circuit up to the transformer T_4 is therefore equivalent to a phase-shifting transformer supplying the potentiometer R.

(4) CONSTRUCTIONAL DETAILS.

In this section the chief constructional features of the three principal types of a.c. potentiometers—the Drysdale-Tinsley, Gall, and Campbell instruments—will be dealt with.

Drysdale-Tinsley Potentiometer.—Fig. 23 shows the arrangement and connections of this instrument as constructed by Messrs. H. Tinsley and Co. The instrument is divided into 6 sections: (*a*) the potentiometer, (*b*) the phase-shifting transformer, (*c*) the dynamometer current indicator, (*d*) the change-over switch for conversion from d.c. to a.c. working, (*e*) the selector switch, and (*f*) the terminal slab.

The potentiometer proper is a standard type of Tinsley universal potentiometer having two dials and a slide wire with transposition circuit, which the author considers to be the best compromise for accurate and rapid working. The first dial has 18 coils of 2 ohms each, which, with the standard working current of 50 mA, gives a p.d. of 0·1 volt per coil. Two brushes move simultaneously over this dial, bridging two coils, and these are connected to the ends of the second dial having 10 coils of 0·4 ohm each, so that the parallel resistance of the combination is 2 ohms, equivalent to that of a single coil of the first dial. The slide wire has a total resistance of about 0·23 ohm and is provided with a scale of 115 divisions, so that each division represents 0·0001 volt (or 100 μV) when the transposition circuit is used, and the total range of the potentiometer is from a few microvolts to 1·8 volts. The coils are of manganin wire double-wound on brass bobbins, and, although they are not perfectly non-inductive, their time-constants are sufficiently nearly equal to avoid readable phase differences. Two keys with locking cams are provided for the standard cell and measuring circuits respectively.

---

* See Reference (24).

The phase-shifting transformer (Fig. 24) is a most important part of the instrument and is fixed at the lower right-hand corner. It consists of a laminated stalloy stator with 48 tunnels, and the windings of the two phases are shown diagrammatically in Fig. 25. The number of coils in each slot is graduated according to a sine law so as to produce a practically uniform magnetic field in the stator tunnel. The rotor has 36 nearly closed slots, and has two windings similarly distributed at right angles. One of these windings is connected through flexible connections to the potentiometer terminals, while the other is permanently connected to a "compensating coil" of resistance and inductance equal to those of the potentiometer circuit including the dynamometer, thus ensuring that the reaction of the rotor is constant for all positions. The rotor is mounted in parallel bearings accurately concentric with the stator, and is provided with a worm wheel and spring worm which can be thrown out of action for quick working, and with a movable stop which permits of a little more than 360° total rotation.

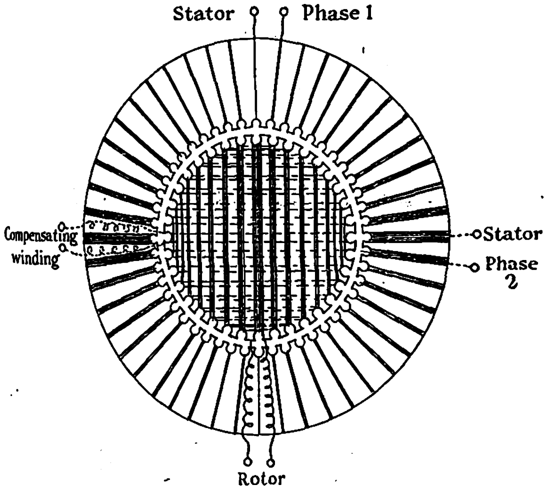

FIG. 25.—Drysdale-Tinsley phase-shifting transformer—winding diagram.

When the phase-splitting has been properly performed, the phase of the rotor p.d. changes by the same angle as that through which the rotor is turned, within an accuracy of about ± 0·1°. The standard primary p.d. is 100 volts and the same transformer will serve with different phase-splitting from 25 to 1 000 cycles per sec., or to 2 000 cycles if the two halves of the primary coils are connected in parallel.

The pointers and dial are of some interest. The dial is divided into two halves, of which the right-hand half is graduated in degrees from zero to 90° lead or lag. The left-hand half is graduated as a cosine scale. A fixed or "axis" pointer is first mounted on the rotor spindle and is in the direction of the magnetic axis of the rotor winding which is connected to the potentiometer. This pointer is of use in phase-splitting. A tightly fitting spring cap carrying four pointers fixed accurately at right angles is then pushed on to the spindle. One of these is marked as the "index" pointer and is used to read off the phase angle directly on the degrees dial. In measuring an impedance, the current is first balanced and the cap is twisted until the "index" pointer is at zero, after which, when the p.d. is balanced this pointer reads the phase angle directly. The opposite pointer is marked "cosine" and directly indicates cos ϕ (the power factor), while the other two pointers at right angles are marked "sine," and read sin ϕ on the cosine scale. The whole arrangement therefore permits of rapid conversion from polar to rectangular co-ordinates without it being necessary to refer to tables, and therefore assists the calculation of the resistance and reactance components, and of the power.

The dynamometer indicator is a standard form of Weston shielded dynamometer having a fiducial mark on its scale corresponding to a current of 50 mA. It is provided with a zero adjustment which enables the pointer to be set exactly to this mark when the dials and slide wire are set to the e.m.f. of a standard cell and the cell is balanced by adjusting the rheostats.

The remaining components need little description. The change-over switch is an 8-pole switch having 4 pairs of contacts connected respectively to a 4-cell accumulator, the secondary of the phase shifter, a moving-coil galvanometer, and a vibration galvanometer respectively. With the switch in one position the accumulator and moving-coil galvanometer are in use, and on turning to the second position the accumulator is replaced by the phase shifter and the moving coil by the vibration galvanometer, so that the instrument is immediately available for either d.c. or a.c. working.

The phase-splitting device consists simply of a sliding-contact dial resistance box having a total resistance of 1 111 ohms and a current-carrying capacity of 0·3 amp., and a plug condenser having a capacity of from 0·001 to 11·11 μF. These are normally connected in series with each other and with one phase of the stator, but for low frequencies the resistance and condenser may be connected in parallel. For the series arrangement the resistance is about 320 ohms and the capacity about 6·9 μF at 50 cycles per sec., the corresponding values at 500 cycles being 740 ohms and 0·03 μF. The theory of phase-splitting is given in the appendices.

Gall Co-ordinate Potentiometer.—In this instrument (Fig. 26) the two potentiometers only are contained in the case, the phase-splitting transformer and dynamometer being external. These potentiometers are of the Crompton or single-dial and slide-wire type with 18 coils each of 2 ohms and a circular slide wire of about 2·4 ohms subdivided to 0·001 volt, with a transposition circuit. These dials and slide wires, as well as the selector switch, are all under a glass cover, the rheostats, plug transposition connections, reversing switches, galvanometer key and terminals being arranged round it. One position of the selector switch marked "test" connects the "in-phase" potentiometer to the secondary of a mutual inductance of 31·82 mH, the primary of which is in series with the circuit of the "quadrature" potentiometer, and which therefore gives balance against 0·5 volt for a frequency of 50 cycles per sec. (or 0·6 volt for 60 cycles, etc.) when the magnitude and phase of the current in the quadrature potentiometer are correct. An additional secondary coil having a mutual inductance of 3·182 mH is employed for frequencies above 180 cycles per sec. The construction of the remainder of the details needs no special description.

Instead of including a pointer dynamometer instrument in the potentiometer, Mr. Gall uses a reflecting dynamometer of somewhat similar construction to the author's torsional wattmeters. The torsion head can be so set that the spot is at some definite point of the scale when the potentiometer is balanced against a standard cell, and the arrangement has the advantage of allowing the observer to see that his potentiometer current is correct at the moment of obtaining balance. On the other hand, the self-contained pointer instrument avoids the risk of errors due to shifting of the scale or instrument, and therefore obviates the need for frequent checking by means of direct current.

FIG. 26.—Gall co-ordinate a.c. potentiometer.

The original phase-splitting device consists, as mentioned on page 346, of a resistance and transformer connected as in Fig. 16, the secondary being reversed so that its induced e.m.f. is in the opposite direction and produces the required change of phase. This is a very simple and satisfactory device for the small current required for the potentiometer circuit, as it is fairly easily adjusted and is less affected by small changes in frequency than the resistance-condenser combination of the author's potentiometer. The possibility of employing it for the latter instrument has recently been considered, although it is somewhat more difficult to carry out with the heavier currents required to magnetize the phase-shifting transformer with its necessary air-gap between stator and rotor. Mr. Gall has, on the other hand, used the resistance-capacity method of phase-splitting in the primary of a transformer supplying the quadrature potentiometer, and has also used it in connection with valves so as to make his potentiometer available for use with valve oscillator supply. This instrument, like the author's form, is constructed by Messrs. H. Tinsley and Co.

Campbell-Larsen Potentiometer.—This instrument has recently been put into commercial instrument form by the Cambridge Instrument Co. and is shown in Fig. 27. As already mentioned, the potentiometer and variable mutual-inductance standard are in separate cases; this allows of the latter being detached for other uses. The potentiometer consists of two dials and a circular slide-wire carrying 10 mA and reading up to 1·8 volts, at the right-hand side of the case; and immediately behind them are a 5-point selector switch for connection to the five pairs of terminals at the back, and a 4-way reversing switch for measuring in the four quadrants. The four dials running down the centre are the frequency-setting dials, which must be set to the known frequency of the supply before measuring, and have a range from 25 to 1 000 cycles per sec. On the left-hand side are two rheostats for adjusting the alternating current, and two for adjusting the auxiliary direct current through the heater, and also a milliammeter, the thermo-junction and heater, the switches and keys for changing from d.c. to a.c. measurement, and terminals for the connection of the a.c. and d.c. supplies, the standard cell, and d.c. and vibration galvanometers or telephone receiver. Two pairs of terminals are provided on the right-hand side for connection to the primary and secondary circuits of the inductometer, which has a logarithmic or constant-accuracy scale from 1 to 100 μH and additional coils extending the range to 11 mH.

FIG. 27.—Campbell-Larsen a.c. potentiometer.

(5) APPLICATIONS OF THE A.C. POTENTIOMETER.

Of all electrical instruments which have been devised, the a.c. potentiometer is by far the most universal in character, and its applications are so numerous that to describe them all in detail would occupy too much space. In what follows, therefore, a general account of these applications will be given, with detailed instructions and examples of only a few of the most important ones. It must be premised that, in common with other devices of a universal character, there is no pretension that the a.c. potentiometer is superior, or even equally accurate or convenient for any given test, to some of the special instruments, but it does allow of nearly all of these tests being made with ample accuracy for most practical purposes, with very little accessory apparatus. The bulk of the applications will be described with reference to the author's polar potentiometer, as it is the only one with which he has had much experience; but the modifications necessary for the rectangular co-ordinate type of instrument will in most cases be obvious and will sometimes be referred to. The only apparatus required is the potentiometer with its source of supply and regulating arrangements, a d.c.

and vibration galvanometer and standard cell, a main voltmeter and frequency meter, a volt box and set of non-inductive resistances, and a few inductances and condensers. All the ordinary d.c. potentiometer measurements can, of course, be made with the instrument and need no description.

We shall assume in what follows that the potentiometer has been fed from the source of supply, and that the phase-splitting or frequency-setting and the tuning of the vibration galvanometer have been correctly adjusted before measurements are commenced.

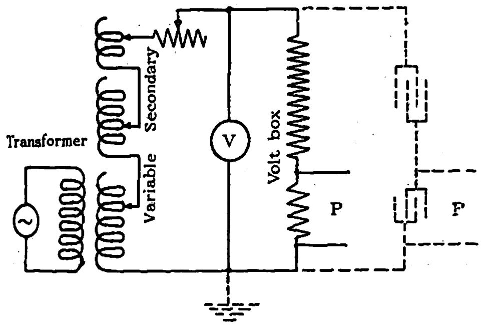

FIG. 28.—Voltmeter calibration.

P.D. Testing and Voltmeter Calibration.—Alternating p.d.'s of any frequency from 25 to 1 000 cycles per sec. (or up to 2 000 cycles with the second phase-shifter) and from 1 mV or less up to 1·8 volts can be measured directly on the potentiometer. For higher voltages any ordinary volt box may be employed, provided that all its coils are either non-inductive or have similar or negligible time-constants (which is always the case for supply frequencies). The connections for voltmeter calibration are shown in Fig. 28, and if the voltmeter under test is not very inductive the phase of the p.d. will change so little as the regulating rheostat is varied for the different readings that little adjustment of the phase shifter is required after the first reading. High accuracy of phase-splitting is not essential in this case, provided that the dynamometer current is adjusted to its standard value when balance is made.

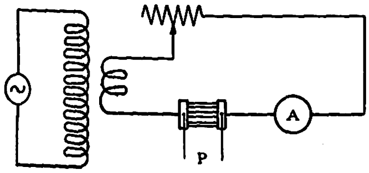

FIG. 29.—Ammeter calibration.

For very high voltages the volt box may be replaced by two condensers in series as shown by the dotted lines, and the circuit should be earthed at the potentiometer side.

Current Testing and Ammeter Calibration.—This can be done in precisely the same manner as for the measurement of direct currents by potentiometer, provided that a set of non-inductive low-resistance standards or "shunts" is available. Fig. 29 shows suitable connections for ammeter calibration in which the current is derived from a transformer fed from the same mains as the potentiometer; if this transformer has good regulation the phase of the current will change very little as its value is altered, so that only a small resetting of the phase shifter is required after the first reading. As in the case of voltmeter calibration, accuracy of the dynamometer current only is essential. In Table 1 are given a set of readings taken on a Kelvin deka-ampere balance, and not only the accuracy of the method but the errors which occur in the balance at high frequencies, due to eddy currents, are shown.

TABLE 1.

Frequency	Kelvin balance reading	P.D. by potentiometer	Current by potentiometer
cycles per sec.	amps.	volt	amps.
0 (d.c.)	20	0·09998	19·996
50	20	0·10002	20·004
600	20	0·1018	20·36
750	20	0·10245	20·49
900	20	0·10275	20·55
1 000	20	0·10315	20·63
1 200	20	0·1043	20·86

If the current wave-form contains large harmonics the readings will not be correct, but the error is inappreciable on fairly sinusoidal supply, as if i_1, i_2, i_3, etc., are the values of the various harmonics, $i = \sqrt{(i_1^2 + i_2^2 + i_3^2 + \text{etc.})}$ and it requires a 14 per cent harmonic to produce 1 per cent error in the value of the current, or a 4·5 per cent harmonic to produce 0·1 per cent error.

Power and Phase Measurement.—Although the a.c. potentiometer cannot compete in convenience and accuracy with a good standard wattmeter, and is only suitable for closely sinusoidal wave-forms, it has the advantage of permitting power measurements to be made over any range with no additional apparatus beyond the shunts and volt boxes required for p.d. and current measurements. Fig. 30 shows the connections for testing the p.d., current and power of any a.c. generator or load, irrespective of its type. The p.d. V is first measured in the ordinary way and the index pointer of the phase shifter is set to zero. On switching over to the "shunt" the magnitude and phase ϕ of the current i can be directly measured and $\cos\phi$ read off from the cosine pointer, from which the power $P = Vi\cos\phi$. When the test is made at various loads on constant-p.d. mains, the phase of the p.d. will remain at zero for all loads, so that it is only necessary to adjust the dials a little at each p.d. reading.

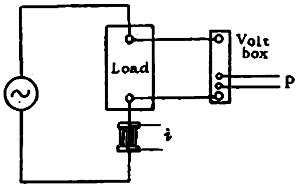

FIG. 30.—Power and phase measurement.

Although the potentiometer can only give correct power measurements on sinusoidal wave-forms, it should be pointed out that there will be no wave-form error if *either* the p.d. *or* the current wave-form singly is sinusoidal. If V_1, V_2, V_3, etc., are the p.d.'s and i_1, i_2, i_3, etc., the currents corresponding to the fundamental and higher harmonics respectively, the power

$$P = V_1 i_1 \cos \phi_1 + V_2 i_2 \cos \phi_2 + V_3 i_3 \cos \phi_3 + \ldots$$

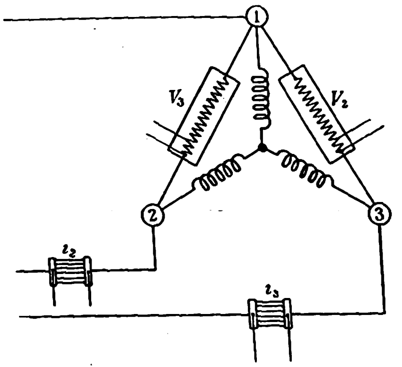

FIG. 31.—Three-phase power measur ment.

If the p.d. is sinusoidal, V_2, V_3, etc., are zero, and if the current is sinusoidal i_2, i_3, etc., are zero; so that in either case $P = V_1 i_1 \cos \phi_1$, which is the power as given by the potentiometer, is correct. There is usually little difficulty in arranging that one or other of these conditions is fulfilled.

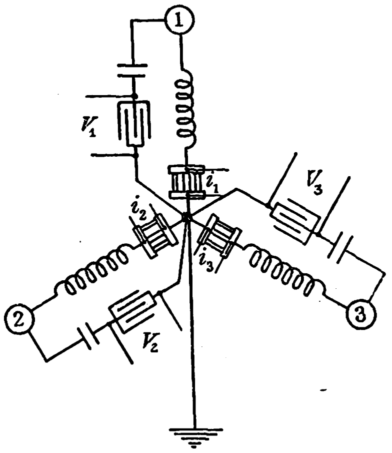

FIG. 32.—Three-phase h.t. generator testing.

Polyphase Power Measurements.—The same method can obviously be applied to polyphase circuits of any type, by measuring the p.d. and current in each phase separately. In the case of a 3-phase circuit, for example, the connections can be made as for the ordinary double-wattmeter method with two equal "shunts" in place of the current coils, and two similar volt boxes, when the power $P = V_3 i_2 \cos \phi + V_2 i_3 \cos \phi'$ (Fig. 31).

The accuracy and convenience of the test in this case are of course inferior to those given by a good polyphase wattmeter, but in the case of large high-voltage and heavy-current generators and motors the a.c. potentiometer may prove to be the only convenient direct method of testing, as wattmeters are difficult to construct and are almost prohibitively costly for the heavy currents now becoming common in large machines. Fig. 32 shows the connections which may be employed in this case. Three equal heavy-current non-inductive resistances are connected at the centre of the star and their common junction is earthed, and three volt boxes or pairs of condensers are connected between this junction and the three terminals of the machine. The whole of the testing circuits are then very nearly at earth potential, and the power is evidently $V_1 i_1 \cos \phi_1 + V_2 i_2 \cos \phi_2 + V_3 i_3 \cos \phi_3$.

Wattmeter and Supply Meter Testing.—Fig. 33 shows the most convenient connections for testing wattmeters and energy meters at any power factor. The supply mains are connected to a step-down transformer for supplying the main coils, and to a phase-shifting transformer, the secondary of which is connected to a variable transformer for the p.d. circuits. The usual shunt and volt box are arranged as shown for connection to the potentiometer, and a small mutual inductance M is included with its primary in the current circuit for accurate checking at zero power factor. The phase-splitting must of course be as accurate as possible for this test. To make a measurement under any desired conditions, the p.d. and current are adjusted to the required values and the rotor of the phase-shifting transformer is turned to an angle corresponding to the desired power factor, after which the potentiometer measurements are made. One of the most important tests is the behaviour of the wattmeter or kWh meter at zero power factor, and this condition can be most accurately secured by turning the phase-shifting transformer until the p.d. across the mutual inductance is in exact phase with that of the supply, after which the p.d. and current measurements are made as before.

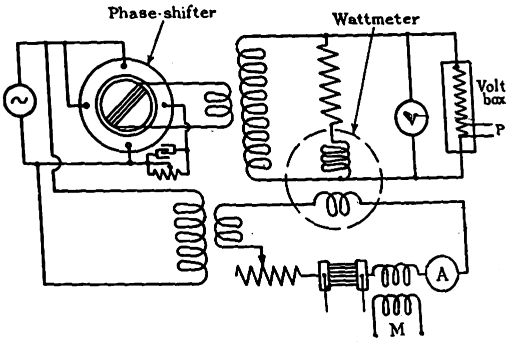

FIG. 33.—Wattmeter and energy meter testing.

Frequency Checking.—The measurement of the frequency employed during the measurements can be fairly accurately effected by the a.c. potentiometer, by measuring the p.d. across the secondary of a mutual inductance in series with its coils. Since this e.m.f. $e_2 = i_1 M\omega = 2\pi i_1 Mf$, we can make up a mutual inductance such that its secondary e.m.f. indicates the frequency directly. For ordinary supply frequencies it is convenient to make 1 volt on the potentiometer correspond to 50 cycles per sec., in which case $M = e_2/(2\pi i_1 f) = 1/(6{\cdot}28 \times 0{\cdot}05 \times 50) = 0{\cdot}0637$ H or 63·7 mH. If the primary of such an inductance is kept permanently connected in series with the a.c. supply from the phase-shifting transformer to the potentiometer, the frequency can be measured at any moment by switching over the selector to the secondary inductance, setting the phase-shifter axis pointer to 90°, and balancing the e.m.f. on the potentiometer. It is evident that accuracy of adjustment of the potentiometer current is not of importance in this test, as variations of it affect the e.m.f. and balancing p.d. equally.

Measurement of Alternating Magnetic Fields.—One of the most useful applications of the potentiometer is to the measurement of alternating magnetic fields, in conditions which would be difficult or impossible with other devices. All that is necessary is to have a suitable search coil and to measure the e.m.f. induced in it by the magnetic field. If A is the mean area of the coil, n the number of turns in it, B the effective or R.M.S. value of the field, and f the frequency, the induced e.m.f

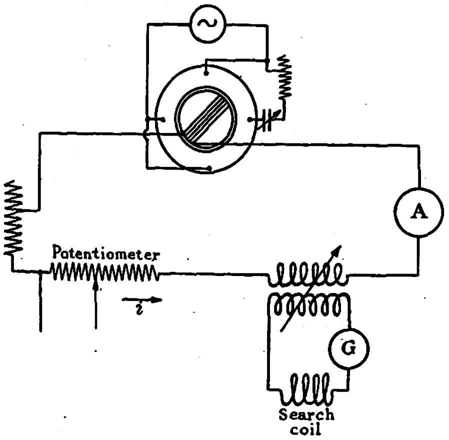

FIG. 34.—Measurement of alternating magnetic fields.

$$e = \frac{2\pi fnAB}{10^8} \text{ volts lagging } 90° \text{ behind the field}$$

or $$B = \frac{10^8 e}{2\pi fnA} \text{ gauss}$$

If we take the ordinary supply frequency of 50 cycles per sec., $2\pi f = 314$, and if $nA = 3\,186$ cm^2 an alternating field of 1 gauss will give 1 volt of e.m.f., which can be measured to about 1 part in 3 000, so that alternating fields of a small fraction of the earth's field can be measured easily and accurately with coils about 10 cm square and having 20 or 30 turns; while fields of the order of 10 000 gauss only require a single loop of wire having an area of a few tenths of 1 cm^2. It is easy, therefore, to measure the induction or flux in a single tooth of an a.c. generator or motor, or the induction in the gap.

The method above described requires a calculation involving the frequency, but by employing a variable mutual inductance standard in series with the potentiometer (Fig. 34), a simple direct-reading method is available. The number of magnetic linkages in the secondary of a mutual inductance is $N = 10^8 Mi$, and since the current in the potentiometer is constant at 0·05 amp., $N = 5 \times 10^6 M$, or 5 maxwells per μH of inductance.

The secondary of the mutual inductance is simply connected to the search coil through a vibration galvanometer or telephone receiver, and balance is secured by turning the phase shifter and varying the mutual inductance, whereupon the number of linkages with the search coil is $5 \times 10^6 M$ and the phase of the magnetic field is the same as that of the potentiometer current. The potentiometer dials are not used in this test, their place being taken by the variable inductance.

A most valuable application of this method is the measurement of stray magnetic fields round the cables and busbars of switchboards, etc., and the author has employed it for investigating the magnetic field around submarine cables fed with alternating current in connection with the "leader gear" method of enabling ships to follow the track of such a cable in a fog. The high conductivity of sea water causes the magnetic field round the cable to be greatly reduced and distorted from the simple circular field produced in a non-conducting medium; and in 1920 the author, with the assistance of Messrs. S. J. Willis and L. Champney, investigated this matter at the Admiralty Research Laboratory, Shandon,* using a barge with a mast at its stern which carried horizontal and vertical search-coils at its upper and lower ends, and also a horizontal boom with electrodes at its lower end for determining the current density in the water. The magnitude and phase of the horizontal and vertical components of the magnetic field above and below water of a cable 3 miles long in the Gareloch, and also of the return current in the water, were determined in relation to the current in the cable by an a.c. potentiometer on the barge, fed by current from the shore through a flexible cable, and it was found, in agreement with theory, that the magnetic field in water progressed in waves having a velocity comparable with that of sound rather than that of light, and that rotating fields were produced in some places above the surface.

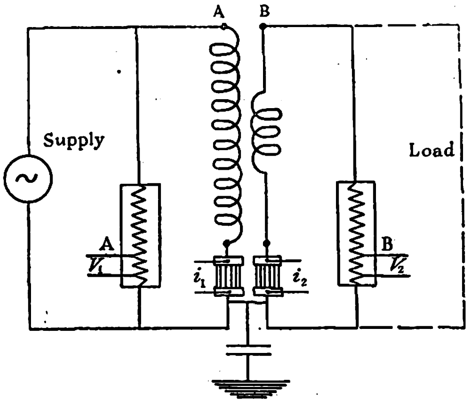

FIG. 35.—Transformer testing.

The propagation of magnetic waves along an iron bar was also investigated by the author in the same manner,† and shown to be of the same character as the propagation of electrical impulses in a submarine cable.

---

* See Reference (25).

† *Ibid.*, (26).

Transformer Testing.—The testing of both power and instrument transformers by the potentiometer is a very simple matter. Fig. 35 shows the connections for the test of an ordinary step-down transformer and is self-explanatory. It is desirable to employ shunts and volt boxes which give approximately equal p.d.'s to the potentiometer, and in the case of high-voltage transformers the volt box may be replaced by a combination of two condensers in series as in Fig. 32. The load may be of any desired magnitude and power factor, and the potentiometer readings enable the vector diagram of primary and secondary voltages and currents to be drawn for each load and the complete behaviour of the transformer to be determined.

In the case of instrument transformers in which the phase displacements are made as small as possible and require to be accurately determined, the connections may be the same, but care should be taken to make the p.d.'s across the two volt boxes exactly equal in magnitude by shunting one or other of them when testing potential transformers. The phase displacement can then be accurately determined by measuring the p.d. v between the two terminals A and B, giving the vector difference, from which the phase displacement $a = 57 \cdot 3\ V/V_1$ degrees.

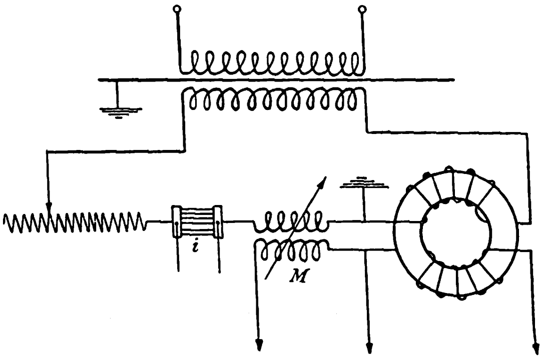

FIG. 36.—Iron testing.

Similarly with current transformers, if care is taken to make the p.d.'s across the two shunts equal in magnitude, which may be effected by shunting one of them, the vector difference giving the phase displacement can be measured on the potentiometer. Two mutual inductances may be substituted for the shunts in this test and the vector difference of their secondary e.m.f.'s measured.

Iron Testing.—The testing of iron stampings in ring form or made up as a magnetic square is effected exactly as in testing an impure mutual inductance, but care must be taken in this case to ensure that *either* the current through the magnetizing coil *or* the p.d. at its terminals is truly sinusoidal, as the non-linear relation of B to H renders it impossible for both to be sinusoidal simultaneously. The most convenient connections generally are as in Fig. 36, which is the same as Fig. 34 except that a moderately large resistance is connected in series with the circuits under test, and the combination is supplied from the secondary of a transformer giving a p.d. of 20 or 30 volts, so that if the p.d. of the supply is closely sinusoidal the resistance swamps the distorting effect of the iron. The current is then measured across the "shunt" in the ordinary manner, from which both H and the number of linkages for a given value of the mutual inductances can be calculated; and the phase-shifter and mutual inductance are then varied until there is balance between the e.m.f.'s of the mutual inductance and the secondary coil on the core, when the number of linkages of the flux with the coil, $N = Mi$ and the phase displacement due to core loss is given directly, from which the core loss can be calculated.

Measurements at Sonic Frequencies.—When a.c. measurements are to be made at frequencies above those of ordinary supply, care must be taken to avoid errors due to inductive and capacitative effects. The circuits to be tested should, as a rule, be a few yards at least away from the potentiometer and vibration galvanometer, and should be connected to the supply and measured through twin flexible or well-twisted leads. This eliminates inductive disturbances, but, unless the circuit under test is very nearly at earth potential, appreciable errors may result from capacity currents from the supply. As the p.d. across the potentiometer is only about 2 volts it can be supplied from a transformer having a low-voltage secondary, and it is desirable to earth the iron of this transformer, or, better still, to have an earthed metallic shield between the windings. In the author's potentiometer the phase-shifting transformer is a fairly effective shield if the rotor iron is earthed, as the windings are embedded in slots and the total p.d. across it is only 12 volts, but it is desirable when making accurate tests on high impedances to supplement this by earthing the potentiometer dial through a condenser. The circuit under test should similarly be supplied from a transformer with earthed shield and giving the minimum secondary p.d. necessary for the test, and the circuit should be connected to earth through a condenser at the most appropriate point. These precautions are especially necessary when telephone receivers are used for detection, as their capacity to the observer's head may cause material error if they are not practically at earth potential. A suitable type of variable shielded "isolating" transformer has been devised by the author.

Inductance Testing.—The measurement of self-inductance is effected in a corresponding manner to that of resistance with the ordinary d.c. potentiometer. The coil to be tested is simply connected in series with a standard non-inductive resistance as in Fig. 30, and supplied with current from a step-down transformer giving about 2 volts on its secondary. The p.d. V_1 is first measured on the potentiometer and the index pointer on the phase shifter is set to zero, after which the p.d. V_2 across the coil is measured and the readings of $\cos\phi$ and $\sin\phi$ are observed on the cross pointers. Then we have $V_1 = Ri$, where R is the non-inductive resistance and i the current, and $V_2 = Zi$, where Z is the impedance of the coil.

Hence $Z = (V_2/V_1)R$, from which the equivalent resistance of the coil $R' = Z\cos\phi$ and reactance $X = Z\sin\phi$, and the inductance $L = Z\sin\phi/(2\pi f)$.

The accuracy of measurement in this case is usually about the accuracy with which $\cos\phi$ and $\sin\phi$ can be read from the dial. It is, of course, desirable to select a standard non-inductive resistance which does not differ very greatly from the impedance of the coil, so that V_2 and V_1 are not very different.

In the case of mutual inductance, the primary is connected in series with the standard resistance, and the second reading is taken on the secondary. Unless the mutual inductance is very impure the second reading will be in exact quadrature with the first, and $M = (V_2/V_1)R/(2\pi f)$. If the mutual inductance is impure the impurity is given by the defect of the phase angle from quadrature, but as the accuracy of the phase indication may not be sufficient for this test, the most satisfactory method is to connect a second variable mutual of perfect purity or known impurity in series with the inductance under test, and to connect the two secondaries in opposition, adjusting the variable inductances until the combined e.m.f. is a minimum. If this e.m.f. is e and that across either of the secondaries singly is E, the phase displacement between the two secondary e.m.f.'s is $57 \cdot 3\ e/E$ degrees.

Capacity Testing.—The simple measurement of capacity is effected in the same manner as that of inductance, the only difference being that the standard non-inductive resistance should generally have a somewhat high value. For the ordinary supply frequency of 50 cycles per sec. the impedance or capacity reactance of a 1-μF condenser is $10^6/314 = 3\,186$ ohms, so that R should be about 1 000 ohms for capacities of a few microfarads, 10 000 ohms for tenths of microfarads, and 1 megohm for capacities of milli-microfarads or under. For sonic frequencies of about 500 cycles the resistance should be about one-tenth of the above values. The condenser is connected in series with the resistance to the secondary of the 2-volt transformer, and the p.d.'s V_1 across the resistance and V_2 across the condenser are measured as before. The index pointer should be set to zero for the first reading, and will be found to be reading nearly 90° lagging for the second balance. Since the capacity reactance or impedance of the condenser $X = 10^6/(C\omega) = (V_2/V_1)R$, $C = 10^6 V_1/(V_2 R\omega)$. The reading on the cosine pointer should give the power factor of the condenser directly, but as it is usually very small, very great care must be taken over the phase-splitting to render the reading of any value, and in any case it can only be regarded as a rough indication.

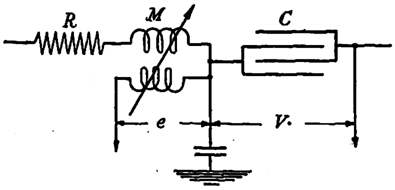

FIG. 37.—Mutual inductance method of testing power factor of condensers.

The power factor can, however, be determined with considerable accuracy by comparison with a variable mutual inductance, provided that it has a high degree of "purity," i.e. absence of internal capacity. For capacities of the order of $0 \cdot 1$ to 100 μF at a frequency of 500 cycles, the condenser may be simply connected in series with the primary of the inductance as in Fig. 37, the secondary being connected so as to give an e.m.f. e in opposition to the p.d. across the condenser. If i is the current across the combination and both the condenser and mutual inductance are perfect, $V = i/(jC\omega)$ and $e = jM\omega i$, so that if M is adjusted until $e = V$, $M = 1/(C\omega^2)$ or $C = 1/(M\omega^2)$, and there will be no p.d. across the condenser and secondary in series. But if the p.d. across the condenser lags less than 90° by a small angle a, $(V - e)$ will not be zero but will be in quadrature with either V or e and can be measured on the potentiometer, and $a = 57 \cdot 3(V - e)/V$ degrees. If $C = 1\ \mu$F (10^{-6} F) and the frequency is 500 cycles per sec., $\omega = 3\,140$ and ω^2 approximately 10^7, so that $M = 10^6/10^7 = 0 \cdot 1$ H (100 mH) for 1 μF, and is inversely proportional to the capacity for a given frequency. Variable mutual-inductance standards are procurable up to 1 H, which enables capacities down to $0 \cdot 1\ \mu$F to be tested at 500 cycles or down to 10 $\mu\mu$F at 1 500 cycles.

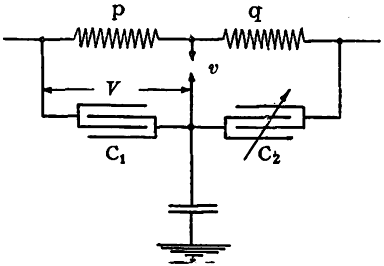

FIG. 38.—Resistance method of testing power factor of condensers.

Very low capacities can, however, best be tested by connecting them in series with an air condenser carefully constructed to avoid absorption across a pair of exactly similar equal-ratio resistances as shown in Fig. 38, where C_1 is the air condenser and C_2 the condenser to be tested, which is supposed to have, or to be adjusted to, the same capacity as C_1. If C_2 were perfect the p.d. v between the junctions of the condensers and of the resistances would be zero, but if not the phase displacement in it would be $2 \times 57 \cdot 3\ v/V$, where V is the p.d. across either of the condensers.

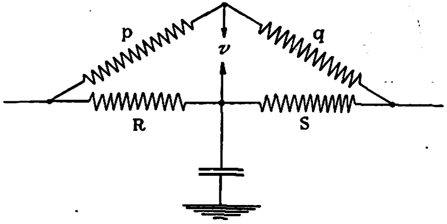

FIG. 39.—Resistance testing.

Phase Displacement in Resistances.—Since resistance standards are the basis of current measurements by the potentiometer, it is of importance to be able to determine whether they are truly non-inductive or, if not, what the phase displacement of their p.d. is, especially in the case of low resistances for heavy-current measurement. Fig. 39 shows the most convenient connections for such tests. The resistance to be tested (R) is connected in series with a resistance S of the same nominal value which is either perfectly non-inductive or has a known phase displacement, and a pair of exactly similar " ratio " resistance coils p and q are connected across the outer terminals in bridge fashion. The p.d. across either R or S is then measured on the potentiometer in the ordinary manner, and also the p.d. between the junctions of p and q and of R and S. The vector diagram of the p.d.'s is then evidently as in Fig. 40, in which the middle vector would obviously be vertical if R and S were exactly equal, and it is therefore evident that the phase displacement ϕ in R is $2 \times 57 \cdot 3\ v/V$ degrees, where v is the perpendicular distance represented by the dotted line and V is the p.d. across either R or S. To ensure accuracy it is advisable to earth the potentiometer and the junction between R and S through condensers, and also to take a second reading of v with p and q interchanged, the mean of the values of v being used if they are different.

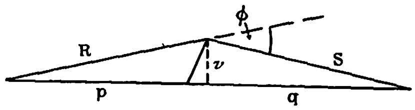

FIG. 40.—Resistance testing—vector diagram.

The only difficulty in such a test is the question of the phase displacement of the standard resistance S, and for this reason methods have sometimes been proposed for comparison with a mutual inductance of assumed perfect purity.

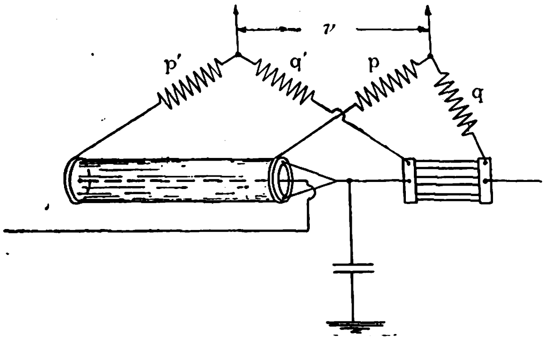

FIG. 41.—Low-resistance testing.

There is no difficulty, however, in making up a perfectly pure resistance for the test on the Moore concentric principle,* and it is far preferable to make measurements of small phase displacements between circuits of similar characteristics, between two resistances, or two inductances. The Moore concentric inductionless resistance is a most valuable device for a.c. testing, but it does not seem to have been sufficiently appreciated. It consists of a tubular resistance in which one current lead is carried through the centre of the tube to the other end, thus confining the magnetic field to the interior so that there is no field outside the tube and therefore no inductive component between any two points on its surface. For low resistances it can, of course, be made of manganin tube, but for tests on coils of tens or hundreds of ohms' resistance the author has employed platinized glass tubes with soldered-on connecting straps. Although these are unsuited for permanent standards they form excellent comparison resistances for phase-displacement tests. Fig. 41 shows the connections for the above test when testing a low resistance against a concentric standard, a second pair of equal ratio coils p' and q' being connected on the Kelvin bridge principle across the inner potential contacts.

Resistance, etc., of Electrolytes.—The testing of electrolytes may be conducted in exactly the same manner as the testing of low resistances (Fig. 41), employing a Moore concentric resistance if it is desired to measure the phase displacement in the liquid. In this connection it is important to note, however, that it is quite useless to attempt to measure such phase displacement between two electrodes in the electrolyte as is usually done, as the polarization effects at the points of entry and exit of the current are quite appreciable. The author has therefore employed a 4-electrode tube as shown in Fig. 42, in which the p.d. is measured across two inner platinum gauze discs having insulating stems passing through the current electrodes. On making a series of careful tests with such electrodes by several methods he was unable to find evidence of any definite phase displacement whatever in sea water, although several observers have given high values for its equivalent dielectric constant.

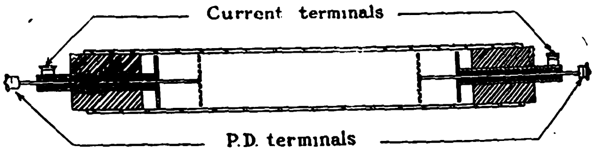

FIG. 42.—Four-electrode tube for measuring resistance of electrolytes.

Cable Testing.—The a.c. potentiometer enables both the characteristics of cables and the distribution of current and p.d. along them to be determined. A cable connected to its receiver has at its sending end a certain impedance Z_1, which can be measured exactly like any other impedance. By the theory of cable transmission we have

$$Z_1 = \frac{(Z_r/Z_0) + \tanh ax}{1 + (Z_r/Z_0) \tanh ax} Z_0$$

where Z_0 is the " characteristic impedance "

$$= \sqrt{[(R + jX)/(G + jB)]}$$

Z_r the impedance of the receiver, a the vector attenuation constant $= \sqrt{[(R + jX)\ (G + jB)]}$ and R, X, G and B the resistance and reactance of the core, and the leakage conductance and susceptance of the sheath respectively. If the receiving end is short-circuited $Z_r = 0$, and $Z_1 = Z_0 \tanh ax = Z_1\underline{/\phi}$, and if it is open-circuited $Z_r = \infty$, and $Z_1' = Z_0/\tanh ax = Z_1'\underline{/\phi'}$, from which

$$Z_0^2 = (R + jX)/(G + jB) = Z_1 Z_1' = Z_1 Z_1' \underline{/\phi + \phi'}$$

and

$$\tanh^2 ax = \tanh^2 x \sqrt{[(R + jX)\ (G + jB)]}$$
$$= Z_1/Z_1' = (Z_1/Z_1') \underline{/\phi - \phi'}$$

---

* See Reference (27).

As the potentiometer measures $Z_1\underline{/\phi}$ and $Z_1'\underline{/\phi'}$ directly, this enables R, X, G and B to be readily calculated. In the case of an artificial cable the p.d. and current can be directly measured as vectors at any point along its length. The magnitude and phase of the current at any point of an actual cable can also be measured by a small hinged ring transformer which can be clipped round the cable, and such a transformer was actually used for measuring the current in the Gareloch cable when investigating the magnetic field round it.

Telephonic Measurements.—These measurements have become of increasing importance of recent years, and acoustic measurement in general is destined to become more and more important. Telephone receivers are essentially small synchronous motors and have the same theory and characteristics, including the circle diagram, as such motors. Up to a few years ago many attempts at testing such receivers by oscillographs were made, but such tests were of comparatively little value owing to the relatively large currents required for oscillographs which involved testing under abnormal conditions. By treating the receiver as an impedance and measuring that impedance with different frequencies up to and above its resonance frequency, we obtain its "circle diagram" immediately, as the potentiometer gives the impedances directly as vectors; and the amount of electrical power put into the receiver and the proportion of it converted into mechanical power can be easily determined from this diagram. Repeating this test with the diaphragm prevented from vibrating by the use of wax, we find by difference the mechanical power imparted to the medium as sound. Conversely, the electrical output of a transmitter when excited by sound from a source fed from the a.c. supply can be measured. The whole performance of a receiver or transmitter over the audible range can be determined from the two sets of measurements obtained in this manner.

(6) INSTALLATION.

On account of the universal character of the a.c. potentiometer it is desirable to pay some attention to its first installation, especially as it is not readily portable and lends itself to measurements on distant circuits. If it is once properly set up in a laboratory with the arrangements for various tests permanently connected in different parts of the room, it will be found most useful, but it will be comparatively little used if it has to be specially set up for any particular test.

The potentiometer should be mounted on a sloping desk on a table near to and facing a wall away from the windows (see Fig. 43) and with a translucent scale at eye-level immediately over it. This table should be 5 or 6 ft. wide, giving room for the phase-splitting devices, a voltmeter and frequency meter, and rheostats for adjusting the p.d. and frequency of the a.c. supply on the right-hand side, and for a standard cell, variable mutual-inductance standard and any small testing circuits on the left. On a shelf below the table the accumulator battery for d.c. testing and the isolating transformer may be placed; and on a shelf on the wall immediately in front of the scale a sensitive moving-coil galvanometer and two vibration galvanometers for low- and high-frequency tests should be mounted and illuminated to give good bright spots on the scale. In the case of the Gall potentiometer, the reflecting dynamometer for indicating the correct potentiometer current is also mounted on this shelf.

The alternators for supplying the potentiometer and testing circuit should be in another room and driven from a battery to ensure steady running. The current should be brought in, preferably by well-twinned or concentric leads, and two other pairs of leads should be provided from the exciting and motor-field circuits to the rheostats on the potentiometer table, so that the p.d. and frequency can be accurately adjusted. It is most important that the alternators should give a good sinusoidal p.d., and the author has been inclined to prefer a d.c. motor with slip-rings for the low-frequency machine, as it generally gives a good wave-form. Now that the frequency of outside a.c. supply is so carefully regulated and the wave-form is so good, low-frequency potentiometer measurements can generally be made satisfactorily with it.

FIG. 43.—Suggested lay-out for test room.

P = potentiometer; G = galvanometers (a.c. and d.c.) and dynamometer.
M = mutual inductance.
P.S. = phase-splitting arrangements.
C.P. = control panel with voltmeter, frequency meter, rheostats and switches.
S = galvanometer shunts.
T.B. = terminal board for experimental leads.

The apparatus and circuits for the measurements required may then be set up on benches at various parts of the room, and well-twinned supply and potential leads run from each of them to a connection board near the potentiometer, from which board four pairs of leads are taken to the terminals so that they can be rapidly brought into circuit by the selector switch. By this arrangement and by having a regulating rheostat or transformer in the supply leads on the potentiometer table, a complete test can often be carried out without the operator having to move from the potentiometer.

As regards accessory apparatus, any good moving-coil galvanometer may be used for d.c. testing, and any sensitive form of vibration galvanometer, provided that it is not responsive to harmonics. The Duddell double-strip vibration galvanometer, although very sensitive and of long range, is not to be recommended as the overtones of the strips are readily excited. For p.d.

measurements ordinary commercial volt boxes are generally satisfactory, but the low resistances or shunts ordinarily employed for current measurements are not sufficiently non-inductive, and the author therefore designed special low resistances for potentiometer work, the larger sizes being on the concentric principle. These resistances have been made for currents up to 40 000 amperes by Messrs. H. Tinsley and Co.

Variable mutual-inductance standards are very valuable accessories for a.c. potentiometer work, as indicated in the above description of tests, and the Campbell or similar forms of inductometer serve excellently. Care must, of course, be taken to see that they are not near the phase-shifting transformer or other highly inductive or heavy-current circuit.

If a little care is taken in setting up the potentiometer and accessory apparatus in some such way as above indicated, its universal properties will soon be appreciated, and it is remarkable how simple and rapid the various tests become after a little practice, when the operator has learnt to visualize its vector properties, as the connections for almost every kind of test are simple and very similar.

In conclusion the author sincerely hopes that this paper, although admittedly most incomplete, will stimulate interest in a.c. potentiometers and help to give them their rightful place as the most valuable of all testing instruments for both engineering and scientific testing. In view of the great need for such an instrument it is remarkable that a.c. potentiometers have been so little used, but the explanation probably lies in the fact that so little has been written in regard to their general application, and it is hoped that the above description of the various tests may do something to remedy this defect.

As to the various types of potentiometers, only three appear to be suited for general testing—the author's, the Campbell-Larsen and the Gall forms. As mentioned at the outset, the author feels bound to maintain the advantage of the polar principle for general purposes, but excellent work can be done by the Campbell and Gall instruments and they have some advantages for measurements on circuits having either very low or very high power factors.

The phase-shifting transformer of the author's potentiometer takes about 0·4 amp. at 100 volts, 50 cycles, and 0·09 amp. at 160 volts, 500 cycles, which precludes its use with small valve oscillators. The Larsen instrument, of course, takes very little power in itself but it is advisable to supply it or the circuit under test from a screened transformer. This involves the use of a certain amount of power, and the measurements are greatly facilitated in many cases by supplying the circuit under test by a phase-shifting transformer, so that it is advantageous as a rule to have a fair amount of power available. Valve oscillators are also liable to give non-sinusoidal wave-forms unless special circuits are employed, which usually reduce their output, and the p.d. from them is generally considerably affected by variations in the testing circuit. It is therefore usually desirable to employ alternators with a good margin of power, in which case the current required for the phase-shifting transformer is not of importance.

If we review the various tests above described and consider the apparatus which would be required to cover them by the ordinary methods, the saving of cost and time in equipping and testing is too overwhelming to need any stress being laid upon it here. The mere fact of being able to measure p.d.'s from a few microvolts to thousands of volts, and currents from fractions of a microampere to 40 000 amperes, either for direct current or for alternating current from 25 to 2 000 cycles, to an accuracy of about 0·1 per cent, with the potentiometer and a set of volt boxes and shunts, is in itself sufficient, without reckoning its application for phase measurements, inductance and capacity testing, etc. Of course, for every special test there is some instrument which for accuracy and convenience is superior to the potentiometer, but the measurements obtained with it are sufficiently accurate for the bulk of practical purposes, and if it is kept set up as indicated its immediate applicability for any test outweighs the superior convenience of a special instrument unless it is already set up for constant use. These features have caused the a.c. potentiometer to be specially appreciated in new countries where the facilities for obtaining special instruments are limited, but they apply with considerable force even to well-equipped test rooms.

APPENDIX I.

THEORY OF THE PHASE-SHIFTING TRANSFORMER.

The function of the phase-shifting transformer is to provide in all positions of the rotor an e.m.f. of constant magnitude but changing in phase by exactly the same angle as that through which the rotor is turned. For this purpose all that is necessary is for the stator to produce a perfect rotating field, but as the 2-phase supply is obtained by splitting the single-phase supply from the mains it is necessary to have some simple means of testing when the current in the split phase is equal in magnitude and in exact quadrature with that in the main phase, and to know what error will be caused by any departure from equality of magnitude or defection from quadrature. Let the current in the main phase $I_1 = I \sin \omega t$, producing an e.m.f. $e_1 = e \sin \omega t$ in the rotor coil when it is parallel to the stator coil carrying the current I_1. Then let the current in the split phase $I_2 = I(1 + \delta) \cos (\omega t - \alpha)$, producing an e.m.f. $e_2 = e(1 + \delta) \cos (\omega t - \alpha)$ in the rotor coil when it is turned into parallelism with the stator coil carrying I_2, or perpendicular to its former position. Here δ is the fractional excess of e_2 over e_1, and α is the angle by which the current I_2 lags behind 90° lead from I_1. Both δ and α are supposed to be so small that their squares may be neglected. Then $e_1 = e \sin \omega t$, and $e_2 = e(1 + \delta) \cos (\omega t - \alpha) = e(1 + \delta) (\cos \omega t + \alpha \sin \omega t)$. When the rotor coil makes a leading angle θ with the direction of I_1 the e.m.f. in it will be

$$\begin{aligned} & e_1 \cos \theta + e_2 \sin \theta \\ & \quad = e\left\{\cos \theta \sin \omega t + (1 + \delta) \sin \theta (\cos \omega t + \alpha \sin \omega t)\right\} \\ & \quad\quad = e\left\{(\cos \theta + \alpha \sin \theta) \sin \omega t + (1 + \delta) \sin \theta \cos \omega t)\right\} \end{aligned}$$

The magnitude of this is

$$e\sqrt{[(\cos\theta + a\sin\theta)^2 + (1+\delta)^2\sin^2\theta]} \\ = e(1 + \tfrac{1}{2}a\sin 2\theta + \delta\sin^2\theta)$$

while the angle of phase lead ϕ is given by

$$\tan\phi = \{(1+\delta)\sin\theta\}/(\cos\theta + a\sin\theta)$$

If δ and a are both zero e is constant, and $\tan\phi = \tan\theta$ or $\phi = \theta$ as is required.

If a only is zero, or the two stator currents are in exact quadrature but differ in magnitude, the e.m.f. increases from e when $\theta = 0$ to $e(1+\delta)$ in the perpendicular direction, as is obvious; and $\tan\phi = (1+\delta)\tan\theta$, from which $\phi - \theta = \Delta\phi = \frac{1}{2}\delta\sin 2\theta$. This means that there is no error in the phase angle when θ is near zero or 90°, and that a maximum error of $\frac{1}{2}\delta$ occurs at 45° and of $-\frac{1}{2}\delta$ at 135°. If δ is $0\cdot01$ or the current in the split phase and the corresponding rotor e.m.f. are 1 per cent higher than in the direct phase, ϕ will be greater than θ by $\frac{1}{2} \times 0\cdot01 \times 57\cdot3 = 0\cdot29°$ at 45°, and less by the same amount at 135°.

If δ only is zero or the stator currents are equal but with a defection a from true quadrature, the e.m.f. $= e(1 + \frac{1}{2}a\sin 2\theta)$ and $\tan\phi = \sin\theta/(\cos\theta + a\sin\theta)$, from which $\Delta\phi = -a\sin^2\theta$. The e.m.f. therefore has a maximum value of $e(1+\frac{1}{2}a)$ at 45° and a minimum of $e(1-\frac{1}{2}a)$ at 135°, and the phase error increases from zero to $-a$ at 90°. Consequently if the two e.m.f.'s at 45° and 135° differ by 1 per cent the maximum error $\Delta\phi = a = 0\cdot01$ radian or $0\cdot57°$ at 90°.

In the general case the e.m.f. $= e(1+\frac{1}{2}a\sin 2\theta + \delta\sin^2\theta)$, which is a maximum or minimum when $\tan 2\theta = a/\delta$, from which the maximum and minimum values of the e.m.f. are

$$e\left\{1 \pm \tfrac{1}{2}a^2/\sqrt{(\delta^2 + a^2)} + \tfrac{1}{2}\delta(1 \pm \delta/\sqrt{(\delta^2+a^2)}\right\}$$

In this case $\Delta\phi = \frac{1}{2}\delta\sin 2\theta - a\sin^2\theta$.

The general conclusion from this investigation is that any departure from equality of magnitude or from quadrature of the two currents produces an elliptical instead of a circular field, and that if the ratio of the maximum to the minimum e.m.f. in the rotor is $(1+a)$, where a is small compared with unity, the maximum deviation in the phase angle from the angle of rotation is a radians or $57\cdot3a°$ or plus or minus half this angle if the scale is set so as to be correct at the best point. A 1 per cent difference between the major and minor axes will therefore produce a maximum phase error of $\pm\ 0\cdot29°$, and if the variation in the rotor e.m.f. is less than $0\cdot3$ per cent the phase angle will be correct within $0\cdot1°$.

An important result of the investigation is the most simple method of adjusting the phase-splitting. As already mentioned, the rotor of the phase-shifter is provided with a fixed pointer (the "axis pointer"), which when at zero indicates that the rotor winding is co-axial with the direct phase of the stator. The dynamometer in series with the potentiometer circuit acts as a voltmeter indicating the rotor e.m.f. If the dynamometer readings are the same when the axis pointer is at zero or 90° this shows that the split-phase current is equal to the main-phase current, and the phase-splitting device can be adjusted until this is the case. On then setting the axis pointer to 45° and 135° successively the two dynamometer readings should also be equal, but if the former is higher the split phase leads by less than 90°, while if it is lower the lead is greater than 90°. A few successive adjustments of the phase-splitting device until the dynamometer readings at 0, 45°, 90° and 135° are all equal ensures that the field is a truly rotating one, and if the maximum difference between these readings is less than $1/2\cdot9$ or $0\cdot32$ per cent the greatest error in the phase angle will be $0\cdot1°$. There is no great difficulty in securing this result if the frequency is kept constant to about $0\cdot1$ per cent.

APPENDIX II.

THEORY OF THE RESISTANCE-CONDENSER PHASE-SPLITTING DEVICE.

The phase-splitting device employed with the a.c. potentiometer is usually a simple combination of a resistance and condenser in series with one of the windings. Since the currents in the two phases are to be equal in magnitude, the impedances of the two circuits must be equal, and since the currents are to be in quadrature the total resistance of the split phase must be equal to the reactance of the direct phase, and the total reactance of the split phase must be equal to the resistance of the direct phase. Hence if R_D and X_D are the resistance and reactance respectively of the direct phase, and R_S and X_S those of the split phase, $R_S = X_D$, and $X_S = -R_D$. If L is the inductance of the stator, C the added capacity and $\omega = 2\pi \times$ frequency, $R_S = L\omega$, or the added resistance must be $L\omega - R_D$. Also $1/(C\omega) - L\omega = R_D$, and the added capacity must be $C = 1/\{(L\omega + R_D)\omega\}$. If R_D is very small compared with the reactance, $L\omega$, the added resistance is $L\omega$ and $C = 1/(L\omega^2)$, so that the resistance is proportional to the frequency and the capacity is inversely proportional to the square of the frequency. Further, if R_D is small compared with $L\omega$, the current in the direct phase is nearly in quadrature with the p.d., so that the split-phase current is nearly in phase with it, and the magnitude of the latter is varied almost entirely by the added resistance, and its phase by the condenser. Fig. 44 gives the actual variation of the phase-splitting resistance and capacity with frequency for one of these instruments. It should be observed that the effective resistance of the phase-shifter coils rises with the frequency, owing to eddy currents in the core, so that the added resistance actually has to be negative when the frequency is above 400 cycles per sec. For such high frequencies the resistance may therefore have to be transferred to the direct phase, and the supply p.d. increased.

In combination with the previous theory of the rotating field, this gives rise to a simple procedure for obtaining correct phase-splitting with the aid of the dynamometer included in the potentiometer. The direct phase is connected to the main supply, which is maintained carefully at its correct p.d. and frequency; the axis pointer is set to zero, which means that the rotor derives its e.m.f. from that phase; and the potentiometer rheostats are adjusted until the dynamometer indicates the standard current of 50 mA. The axis pointer is then set to 90° and the phase-splitting resistance adjusted until the current is the same, which indicates that the magnitudes of the currents in the two phases are equal. Next, the axis pointer is set to 45° and if the dynamometer reading is higher this means that the current in the split phase leads by less than 90° and the phase-splitting capacity must be reduced. By a few successive adjustments of the resistance at 90° and of the capacity at 45° a condition is reached in which the dynamometer reading is the same at 0, 45°, 90°, 135° and 180° within 0·1 per cent, when the potentiometer will be in adjustment and its phase indications will be correct to within ± 0·1°.

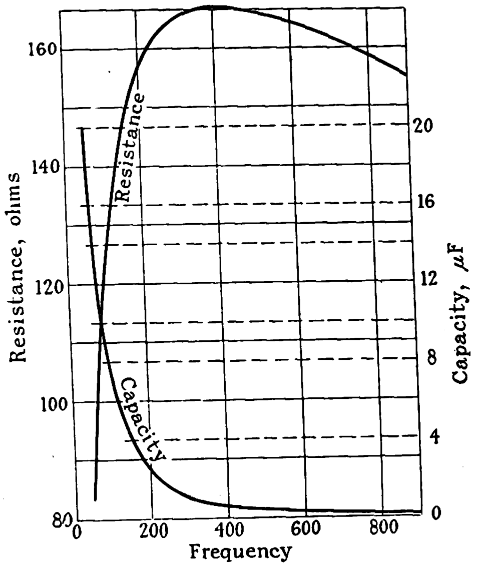

FIG. 44.—Curves of phase-splitting values.

ADDENDUM.

(*Received* 23*rd November*, 1929.)

A successful application has just been made of the principle of the Gall phase-splitting transformer to the author's potentiometer, which will probably result in simplification of the procedure and in reduced influence of small frequency variations.

Discussion before the Meter and Instrument Section, 6th December, 1929.

Prof. W. C. Clinton: The question of alternating-current measurement by potentiometer methods is again engaging considerable attention, and the author is the pioneer inventor of apparatus for this purpose, at any rate as far as this country is concerned. Although harmonics are not likely nowadays to give much trouble, there are special cases in which they become of importance. Would it be possible to measure these harmonics separately, preferably, perhaps, on a co-ordinate arrangement, without too much alteration and adjustment of the circuits and apparatus? With reference to screening, if the methods specified are to be used with confidence at frequencies of, say, over 5 000 cycles per sec., will it not be necessary to consider the arrangement and connection of screens, with the same care as is now employed in the design of high-frequency bridges?

Prof. J. T. MacGregor-Morris: Referring to Dr. Kennelly's demonstration potentiometer, such an instrument was constructed at East London College some 15 years ago; and in order to minimize stray magnetic fields due to the return leads of the two phases, I added two return-current sheets: one in phase A, folded back underneath but insulated from the main sheet, and the other in phase B, folded back at right angles and again insulated from the other sheets. This arrangement largely reduced the stray fields of the two circuits A and B. In this arrangement, therefore, the four sets of manganin leading-in wires appear only on two sides of the square. Unfortunately, we did not devote sufficient time to obtaining the necessary technique, and the apparatus has not been employed for many years. I think that some trouble was experienced in holding the leads in the correct positions. In view, however, of the demonstration potentiometer shown by the author, the use of a light arm, centred at the centre of the square and carrying a slide, but with no slide-wire or phase-shifter, would very materially assist in its use, and I propose to attempt its further development in the near future. Having used a Drysdale form of potentiometer in a fair number of measurements, I feel that one is limited very definitely by the accuracy of the dynamometer, which should indicate 50 milliamperes flowing through the slide-wire. The percentage accuracy of the measurements would appear to me to depend entirely upon the accuracy of the dynamometer when reading 50 milliamperes. A 1 per cent change in the current only gives 1½ mm alteration of the position of the pointer, and hence a precision of one part in 400 is all that is possible; and there is also the question as to the constancy of the dynamometer with temperature-changes and other variations. I am aware that it can be calibrated with direct current, but this has to be done with the current flowing first in one direction and then in the other, and the mean value taken. Referring to the vibration galvanometer and the constancy of the frequency of the a.c. supply, I find difficulty, when trying to obtain the most perfect balance, in deciding whether the deflection of the vibration galvanometer has been reduced practically to zero owing to the actual potential difference having been reduced to zero, or owing to a frequency-change of the supply affecting the sensitivity of the response of the vibration galvanometer. Since a vibration galvanometer does not indicate whether the measured a.c. potential difference is higher or lower than the corresponding quantity for the slide-wire, is it not possible to use a stroboscopic disc driven by a synchronous motor (say of the Everett-Edgcumbe Warren type) for examining the phase of the deflection?

Mr. R. S. J. Spilsbury: The author states that his a.c. potentiometer can be referred to a standard cell in the same way as the d.c. instrument. This does not seem to be quite correct, for the assumption is implicitly made that the reading of the dynamometer is the same for both alternating and direct currents of the same value. This condition can quite easily be obtained by paying attention to magnetic shielding and eliminating solid metal near the coils, but it is a much less simple thing to check than the correctness of the resistance ratios of the d.c. potentiometer. With regard to the accuracy with which phase angles can be determined, the author's reference to 0·1 degree is, I think, a little optimistic. It must be remembered that the error includes any error in the phase-splitting, in the reading of the pointer, and in the drawing of the scale. I believe I am right in saying that the phase-shifter scales of commercial instruments are drawn by trial, and are not scales of geometrical degrees: certainly some which I have seen have not been regular. It has to be borne in mind that the phase-splitting is very critical with frequency, as shown by Fig. 44; and unless the power is taken from a good battery-driven alternator, the instrument can be a most difficult one to operate, as the phase-split continually varies. I would suggest, therefore, that in practice the error will be nearer to 0·5 degree than to 0·1 degree. The a.c. potentiometer, while invaluable for research, is not well suited for test work or instrument calibration, except in cases where only a single instrument can be afforded. For instance, the test of a high-power alternator which the author illustrates would involve three measurements of current and three of voltage, each consisting of two settings, in order to obtain a single value of the output in kilowatts; on the commercial load on which large turbo-alternators must be tested, conditions would be varying during the readings, while the amount of calculation necessary to reduce the results would be considerable. The type of work for which the instrument seems to be admirably suited is the investigation of fields round cables, as mentioned in the paper: such work could hardly be done with any other instrument, and many problems of this type are met with in research.

Mr. F. D. Smith: It is evident from the author's description of the a.c. potentiometer in its various forms that the instrument has reached an advanced stage of development and that there is not much more to be gained in accuracy and convenience. There is, however, an urgent need for an extension of its range to radio frequencies. The measurement of phase at radio frequencies is becoming more and more important and, apart from the cathode-ray oscillograph and experimental apparatus of the kind shown in Figs. 21 and 22, there is little available for the purpose. The fundamental principles which must determine the design of an a.c. potentiometer for radio frequencies are now well understood. The possible sources of error are those common to all radio-frequency measurements, and the remedies and precautions to be taken are similar. In a compact assembly of apparatus, there exist capacities between the component parts which present alternative paths for the flow of alternating current. Consider a potentiometer whose upper limit of frequency is 1 000 cycles per sec. and assume that the impedance of some part of it is 1 000 ohms. A capacity of 100 $\mu\mu$F in parallel with this impedance has a reactance of 1 600 000 ohms at 1 000 cycles per sec., and does not introduce any appreciable error. If such a potentiometer is used at 1 000 000 cycles per sec., the reactance of the condenser falls to 1 600 ohms and it becomes comparable with the impedances of the components of the potentiometer. The obvious remedy is to design these components to have impedances of 10 ohms or less, whereupon the shunting effect of the stray capacities is no longer serious. The high-frequency potentiometer shown in Fig. 21 was designed with this general principle in mind. The two pairs of Helmholtz coils which produce the rotating field have only 6 turns of wire each, and the components of the phase-splitting circuit are of similar impedance. Up to 50 000 cycles per sec. the potentiometer can be used without screens; and very simple screens suffice for a considerable range above this frequency. It is, of course, essential to use screens if the greatest possible accuracy is to be obtained. The use of low-impedance components necessarily involves the use of heavy currents in order to gain the necessary sensitiveness. There is no objection to this, because the power consumption in the potentiometer need not be greater than that in a high-impedance potentiometer supplied with a small alternating current. I have found that alternating currents of 10 amperes may be maintained in the 6-turn coils (Fig. 21) with a very moderate expenditure of power. I hope that the author will follow up his pioneer work on the a.c. potentiometer by extending its range to radio frequencies.

Dr. A. H. Davis: I am chiefly interested in audio-frequency measurements for acoustical purposes, the range required being up to, say, 5 000 cycles, or, preferably, to 20 000 cycles per sec. The ear, however, is not very sensitive to changes of intensity, and great precision of the measurement is not often necessary. The author states that most of the instruments described in the paper have an upper limit of 2 000 cycles per sec. Presumably this is due to practical considerations, as the principles appear to be general. In any case, however, it is a low limit for acoustical work. I should like to know whether any of the instruments with which the author deals would, in fact, give substantially accurate results for acoustical measurements well above the 2 000-cycle limit. For instance, the Larsen type involves a resistance and a mutual inductance which can each be made reasonably accurate at much higher frequencies. It is true that the Campbell frequency-setting device which the author has shown us does not go higher, but it is not essential to the Larsen potentiometer if there is any difficulty in extending its application. The apparatus of Messrs. B. S. and F. D. Smith deals, of course, with high frequencies, but its scale appears to be a short linear one, insufficient to deal with the very wide ranges in amplitude which are usual in acoustical work.

Mr. R. M. Longman: I have recently had to consider the purchase of equipment of the type dealt with in the paper, and, so far as I can gather, my decision as to type has been to a great extent confirmed by the author. I have been responsible for the purchasing of two a.c. potentiometer equipments, the first, immediately prior to the outbreak of the War, being of the Tinsley-Drysdale pattern as described by the author. Unfortunately, owing to the War, I was unable to complete the necessary a.c. equipment, and it was later transferred to a more fully equipped laboratory, where I understand it has given excellent results and is in regular use. When considering the question recently, I decided upon the Gall co-ordinate potentiometer. This instrument, although delivered, is not yet in full use. With a little practice, it is extraordinary how quickly and accurately results can be obtained with either of these instruments, although they appear to have a number of rather complicated parts. I am proposing to operate thise quipment through suitable transformers direct from the supply mains, and the question arises as to the steadiness of the supply system. It is most important that such equipments should be suitable for satisfactory operation under these conditions.

Mr. W. H. Grinsted: It may be of interest to mention the device used by Mr. Wigan in connection with the indicating telephone in audio-frequency potentiometer measurements, referred to by him as the "listening point." * This "listening point" consists of an ordinary telephone receiver associated with a microphone, the observer's telephone being actually in the secondary circuit so formed, instead of directly in the indicating circuit of the potentiometer. This simple device is very effective: it provides a fair degree of amplification and it removes the difficulties due to the earth capacities of the telephone leads. I should like also to draw attention to another method of obtaining two currents, e.m.f.'s or other vector quantities in quadrature. If we have two vector quantities of equal magnitude but with any suitable phase difference, and if we can by some means form a quantity corresponding with their sum and another quantity corresponding with their difference, then these two latter quantities are in quadrature. This is a scheme which I have found useful in an alternating-current measuring device other than a potentiometer, and it would be interesting if the author could say whether it has ever found application in potentiometers.

Mr. F. L. Best: The author has, on previous occasions regretted the fact that the a.c. potentiometer, in any form, has not proved a popular instrument, and I think the probable reason for this is that its capabilities and limitations have not been understood—far less appreciated—by those who could gain by its use. The ideal form of a.c. potentiometer is one in which the polar ordinate and the phase angle are measured. The author's potentiometer is an instrument of this type. So far, potentiometers designed to enable the measurement of a single vector and its phase angle have not permitted the phase angle to be measured with any great degree of precision. The co-ordinate potentiometer undoubtedly does enable the phase angle—and, what is often more important, differences in phase angle—to be measured with a fairly high degree of accuracy. In the co-ordinate potentiometer of the Campbell-Larsen type, for instance, the top dial reads in steps of 0·1 volt, whilst the slide-wire reads down to graduated divisions each having a value of 100 μV. This applies to both the in-phase and quadrature components. Since even small departures or differences in phase angle are bound to alter either the in-phase or the quadrature components by relatively large amounts, the improved measurement of phase angle is clear. With regard to the standardization of the reference current, the author has almost said that this is effected by reference to the d.c. standard cell. Undoubtedly he is fully aware of the fact that this reference is via the dynamometer in the case of his own potentiometer, but I think that there is still a good deal of justification for the assertion. In the case of the Campbell-Larsen instrument, the reference current is also standardized by reference to the standard cell, but via the thermal convertor. In the absence of any piece of apparatus which can take the place in the a.c. circuit corresponding to that occupied by the standard cell in the d.c. circuit, dynamometers or thermal convertors must inevitably be used. Generally speaking, it is possible to know the performance of such apparatus at the essential frequencies, and the errors resulting need not be large. In the practical realization of the theories, the Campbell-Larsen potentiometer appears in the form of two distinct and separable instruments: the resistance unit, which can be used as a d.c. potentiometer, and the Campbell standard mutual inductometer (with long logarithmic scale). The latter, when separated from the combination which it forms with the resistance unit to constitute the a.c. potentiometer, is available for all the various well-known high-frequency bridges due to Campbell, Wein, Carey Foster and others. Considering a.c. potentiometers as a whole, there is no general opinion prevailing as regards the accuracy obtainable. Faced with carrying out a piece of work where the potentiometer might conceivably be employed, few electrical engineers would be able to say whether the desired accuracy was obtainable. References to makers, obviously, should put one in possession of this information, but the instrument finds no place in any of the specifications for standards, although it falls in a class which should enable it to qualify as the subject for a British Standard Specification. The accuracy of the Campbell-Larsen instrument is, for the resistance unit, 0·1 per cent for all dials; the slide-wire is accurate at all marked points to 10 μV. The standardization of the mutual inductance is accurate to 0·1 per cent for the dials, the scale being accurate to 0·1 μH at each marked point. Each division of the scale corresponds to 1 μH and 100 μV when associated with the a.c. potentiometer. The scale is accurate to 10 μV at all points. These figures apply from zero frequency to 2 000 cycles per sec.

---

* See *Electrician*, 1929, vol. 103, p. 561.

Mr. E. W. Hill: With regard to fundamentals, I admit having had a feeling of distrust when I first considered the principle of the a.c. potentiometer. This was due to the fact that, while measurements on a d.c. potentiometer are referred directly to a primary standard of e.m.f., there is an impassable barrier in the way of this direct reference in the a.c. potentiometer. This barrier has to be bridged by some artifice which always involves an assumption. In the a.c. potentiometer the reference back to the primary d.c. standard has always to proceed via some such link as the dynamometer ammeter, which we have to assume behaves precisely the same on alternating as it does on direct current. This is a point which has been emphasized by several speakers, but, on the other hand, we should reflect that it is a difficulty which is not peculiar to the a.c. potentiometer, but is common to practically all a.c. measuring instruments in respect of the original source of their standardization. With reference to the section dealing with polyphase power measurements, I do not think the author's implication regarding the apparent difficulty of using wattmeters is justified; on the contrary, the indicating wattmeter method is perfectly practicable for any magnitude of current, and for most voltages, by making use of carefully calibrated current and potential transformers. In the section dealing with potential transformer testing, the expression "shunting one or other of them" does not seem to be quite clear, and I shall be obliged if the author will give some further explanation. With regard to the phase-shifting transformer, according to my experience there seems to be difficulty in obtaining from it a really constant e.m.f. for all positions of the rotor. Using the phase-splitting method described on a single-phase supply, it is essential, according to the author, to maintain the frequency within 0·1 per cent of constancy. In practice, this is certainly not always easy. On the other hand, this frequency difficulty can be obviated by employing a polyphase supply on a suitably constructed phase-shifter, but I have never found it possible, even then, to get reasonably constant e.m.f. from the stator. These objections may not be very serious, because it is always within one's power to make, from time to time, the adjustment necessary to keep the reading of the dynamometer ammeter steady. The a.c. potentiometer as described seems unsurpassed as a general-purpose apparatus; but for routine testing work of a specialized nature, such as is required in a factory or a supply undertaking's test room, it must give way, from considerations of convenience, to indicating wattmeters used in conjunction with other special-purpose apparatus, such as rotating standards, etc. It would, however, be most useful both as a standard of reference for such routine apparatus and as an instrument of research.

Mr. D. C. Gall (*communicated*): After several years of experience with the a.c. potentiometer, I have found it an ideal instrument for investigational work involving the measurement of current, voltage, power, flux and torque in all the various manifestations. It is, however, inferior to a bridge arrangement for the measurement of circuit constants, e.g. inductance, capacity and effective resistance, unless these are variable with current, etc. As regards the limitations of the instrument, the chief defect of the author's instrument is the phase-shifter.

This depends upon a phase-splitting appliance which is essentially a frequency device, and the phase-splitting and, consequently, the angles indicated vary with frequency fluctuations. Further, the least count of the phase-shifter is 1°, which may be subdivided by the worm to, say, 0·1°. This corresponds to a vector magnitude of approximately 1 in 600. Thus the accuracy with which the phase-shifter can be set limits the accuracy with which a voltage can be balanced. I am aware that a finer setting than this can be obtained, but it is tedious, and in use a certain jumpiness, when approaching balance, is found to arise from this cause. A second, and finer, phase-shifting dial is really required, which would subdivide to, say, 0·01°. There would seem to be no great difficulty in obtaining this by the obvious means of two superimposed fields with a small time or space displacement. A further difficulty is the stray field from the phase-shifter. This can be very perplexing in its effects, since part of it rotates with the rotor and part is stationary. For this reason I consider that the strongly magnetized parts should be remote from the instrument. The phase-splitting defects are most noticeable at large phase displacements. Thus low power factors are least accurately measured and, where circuits are isolated, triangular measurements cannot be made to check small angles. For this reason I think the co-ordinate type of potentiometer a considerable advantage, particularly for the measurement of power at low power factors, since the power is given by the sum of two products without involving any angle, whereas with the Drysdale type of potentiometer the angle, which is not very accurately known, is involved. The ideal form is a combination of the author's potentiometer and the co-ordinate type, i.e. a co-ordinate potentiometer provided with a suitable phase-shifter. The whole potentiometer can then be rotated to any phase position, where power and wattless components can be measured separately on the two potentiometers with the greatest accuracy and without the complication of an inclined system of co-ordinates. The power taken by the author's phase-shifter makes the use of the potentiometer upon valve circuits rather difficult. With the co-ordinate type of potentiometer, the phase-splitting can be done on the input side of the supply valves, and great economy in phase-splitting results. Further, the phase-splitting can be made independent of frequency. Phase-shifting arrangements can be also inserted there to bring about the conditions, mentioned above, of a combined Drysdale and co-ordinate potentiometer.

Mr. A. Campbell (*communicated*): In 1900 I constructed a phase turner for measuring the magnitudes and phases of unknown alternating voltages with the help of an electrostatic voltmeter.* This instrument embodied an essential part of some modern a.c. potentiometers, namely, a phase-splitter. This was of the simplest type, but could be easily set correctly for any unknown frequency. The simple Larsen type of instrument requires very little power to work it, as no external phase-splitter is necessary, the instrument being in itself the simplest form of phase-splitter. Even with the elaboration of a loop shunt which I have added, it only takes a fraction of a watt, and is thus quite suitable for use with an ordinary valve oscillator as source of power. The methods of measurement described in the latter part of the paper are very interesting, and the straightforward simplicity of the potentiometer tests is much in their favour. In some cases, however, bridge null methods would prove easier. The results obtained on the resistance of electrolytes should be of interest to physical chemists.

Dr. C. V. Drysdale (*in reply*): I should like to express my appreciation of the interest which has been manifested in the subject. The points raised in the discussion are all of interest and show that the speakers are fully alive to the importance and limitations of a.c. potentiometer measurements.

Prof. Clinton raised the important question of harmonics, and asked whether they can be separately measured. Unfortunately this does not appear to be generally possible, for the fundamental reason that every form of a.c. potentiometer involves a phase-changing device, and there is at present no method known or conceivable for altering the phase of a non-sinusoidal potential difference, without changing its form or the ratio of the harmonics to the fundamental. If the supply to the potentiometer is sinusoidal and the p.d. to be measured is distorted by the nature of the load, then when balance is secured with a vibration galvanometer tuned to the fundamental, the harmonics in the p.d. will be unbalanced. They may be detected by a telephone receiver and separately measured by a second vibration galvanometer tuned to any given harmonic. If, however, the wave-form of the supply p.d. has no harmonics exceeding 2 or 3 per cent of the fundamental, they may be neglected in all ordinary measurements. The importance of screening and earthing in high-frequency testing is referred to in Section (5) of the paper.

Prof. MacGregor-Morris's method of constructing the Kennelly demonstration potentiometer is ingenious and appears to be quite sound in principle. I am surprised that he should have experienced difficulties with it. Apart from contact troubles, which surely are not insurmountable, the only source of error would probably be non-uniform current distribution in the sheet. It should be possible easily to determine the inaccuracy by connecting one phase at a time and plotting the equipotential lines with two contacts and a telephone. If these lines are found to be straight and perpendicular there would seem to be no cause for serious error; if not, adjustment of the leading-in wires should rectify them. Using the dynamometer, I have never had any difficulty in adjusting the current to within ± 0·1 per cent, and Prof. MacGregor-Morris's remarks concerning the change of sensitiveness of the vibration galvanometer lead me to think that all his troubles are due to insufficient constancy of the supply frequency; variations are extremely likely to occur in an educational laboratory. In the paper, emphasis has been laid on the necessity for constancy of frequency to within ± ¼ per cent, and it may be pointed out that this constancy is needed not only for the potentiometer but also for the circuits under test, since the impedance of the latter varies with the frequency. I therefore think it better to concentrate attention on securing a constant frequency, rather than on the development of stroboscopic or other devices for observing the galvanometer; especially in view of the fact that the phase of the galvanometer oscillation changes extremely rapidly from lead to lag as the frequency passes the resonance point.

---

* See *Electrician*, 1901, vol. 46, p. 399.

Mr. Spilsbury is quite correct in stating that the comparison with the standard cell is vitiated by any errors in the dynamometer, but as the current is only 0·05 ampere there is no difficulty in avoiding eddy-current errors by reasonably careful construction. The dynamometer actually used is a Weston standard shielded instrument. As to the accuracy of phase measurement, the dial can of course be engine-divided, but on account of the non-uniformity of the cosine scale it is reproduced from a standard dial, and in all the instruments which have passed through my hands it has been accurate to 0·1°. Reference should be made to my paper, "The Alternate-Current Potentiometer as a Standard Instrument,"* in which Certificates of Test by the national Physical Laboratory of one of the author's potentiometers at 1 000 cycles per sec. are reproduced. Out of six measurements of phase angle, four showed no error, one an error of 0·1° and one of 0·2°. Mr. Spilsbury, having the resources of the National Physical Laboratory at his command, naturally prefers to calibrate instruments by comparison with its excellent standards; but if he were working in an ordinary test-room he would probably be thankful to be able to make use of the potentiometer. I quite agree that direct measurement of 3-phase currents by a double wattmeter is distinctly preferable, but until the last year or two the ratio and especially the phase errors of current transformers were too large for accurate measurements, and heavy-current wattmeters were costly and liable to eddy-current errors. Now that we have mumetal current transformers of high accuracy, the situation is changed, but the potentiometer may still be of great service when the resources of the test-room are inadequate, and it must be remembered that it enables a large number of other measurements (e.g. of gap or leakage flux) to be made simultaneously with measurement of output. From the designer's point of view, the ability to measure almost every detail of the performance of the machine is a great asset.

Mr. F. D. Smith's emphasis on the value of a suitable a.c. potentiometer for high-frequency measurements is justified, and the simple device due to Mr. B. S. Smith and himself is the best so far produced. Several years ago I planned a high-frequency potentiometer on similar lines to my ordinary potentiometer, but employing the Moore concentric non-inductive principle for the coils and slide-wire. Unfortunately, there has been no opportunity for constructing this instrument, but there should be no great difficulty in making an accurate a.c. potentiometer for radio-frequencies, although considerable precautions would naturally have to be taken in its use.

Dr. Davis mentions his need of an instrument for frequencies up to 5 000 or even 20 000 cycles per sec., and there is no reason why any of the potentiometers described in the paper should not be modified to work with such frequencies. During the past few years the constancy of frequency of a.c. supplies has become remarkably high, so that they can be satisfactorily employed with the potentiometer. They are, however, liable to sudden small fluctuations of p.d. when heavy loads are switched on or off.

Mr. Grinsted's method of obtaining the quadrature relation is quite correct in principle. I do not think that it has actually been applied to a.c. potentiometers, though this should not be difficult. On the whole, however, I am inclined to think that Mr. Gall's transformer device supplies the best method of phase-splitting. It is the simplest and the least affected by frequency variations; I have recently applied it in place of the resistance-condenser combination for feeding the phase-shifting transformer.

Mr. Best's information concerning the Campbell-Larsen potentiometer is of interest, and I am in general agreement with him. The great simplicity of this instrument, which is ready for use immediately the dials are set for the known frequency, is a most attractive feature. Mr. Campbell's ingenious thermo-current indicator has great advantages in its low power consumption and suitability for high-frequency working, where the inductance of the dynamometer would be objectionable. On the other hand, I must adhere to my objection to the rectangular co-ordinate principle for general measurements, and I am quite sure that the average user would rarely employ such a potentiometer if he had both types available, unless it were supplemented by a phase-shifting transformer to bring any desired p.d. into phase. Such a combination is equivalent to a polar potentiometer with a rectangular co-ordinate addition, which is undoubtedly of value for measurements of small phase displacements. There is no doubt that a combination of the polar and rectangular principles gives rise to the most perfect universal potentiometer. I have used a variable mutual-inductance standard in combination with the polar potentiometer for several tests, especially those relating to magnetic fields. This combination is, in my opinion, the best and most convenient for all-round practical testing, but this may be a bias due to greater familiarity with it.

For power measurements Mr. Hill prefers a wattmeter with current transformers to the potentiometer, and I am in agreement with him provided that suitable instruments are available. As emphasized in the paper, I do not pretend that the potentiometer or any other universal instrument can be as good for any particular test, as an instrument specially devised for that test. In my opinion, however, a device which enables a measurement to be made in the test-room when the special instrument is not available is of very great value. As Mr. Hill has found, the phase-shifting transformer should not be excited from a polyphase supply, for the latter may not be perfectly balanced. The use of Mr. Gall's phase-splitting transformer will probably remove the objection to single-phase working.

My reference on page 354 to "shunting" one or other of the volt boxes when testing p.d. transformers was rather cursory, and seems to have been misunderstood. The shunt should be connected across the "output" terminals of one or other volt box, so as to lower the resistance of, and consequently the p.d. across, the section connected to the potentiometer.

I am in general agreement also with Mr. Gall's remarks, to which many of the above comments apply. In common with others, including myself, who have had experience with a.c. potentiometers, he has come to the conclusion that the triple combination of phase-shifter, potentiometer, and variable inductometer is the most perfect; the only question is as to whether the bulk of the measurements are to be taken on the polar or the rectangular combination. I prefer the former alternative, but such a combination would allow each user to suit himself. Mr. Gall refers to the influence on the circuits of the stray field of the phase-shifting transformer. This has not proved serious, even with the open form of transformer hitherto used. I have, however, recently produced a considerably improved transformer which is totally enclosed in iron, has a smaller stray field, and absorbs far less power. The question of power, raised both by Mr. Gall and Mr. Campbell, is of great importance when valve oscillators are used, as is almost imperative for high frequencies. From this point of view, the Campbell-Larsen instrument is at first sight the more attractive, but I am quite sure that some form of phase-shifting transformer is essential for convenient working, and the improvements referred to above should bring it within the compass of valve oscillators of moderate output.

---

* *Electrician*, 1915, vol. 75, p. 157.

In conclusion, I should like again to express my appreciation of the skill and ingenuity with which Mr. Campbell, Mr. Gall and others have attacked this important problem, and my hope that this paper and discussion will give an impetus to the more general use of a.c. potentiometers. I should like also to express my thanks to Messrs. H. Tinsley and Co. and the Cambridge Instrument Co. for the loan of the potentiometers exhibited at the meeting, and to Mr. S. J. Willis for arranging the experiments with the demonstration polar potentiometer, which I think should prove of great value for teaching purposes.

THE IMPEDANCE AND POWER LOSSES OF THREE-PHASE OVERHEAD LINES.[*]

By P. D. MORGAN, M.Sc., and S. WHITEHEAD, M.A., Associate Members.

[TECHNICAL REPORT (F/T37) FIRST RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION 23RD JULY, AND IN FINAL FORM 6TH NOVEMBER, 1929.]

SUMMARY.

This report deals with two problems of primary importance in connection with the transmission of three-phase power by high voltage lines, viz.:—

(a) The effects of transposing the line conductors on the operation characteristics and power losses.[†]
(b) The impedance of a line conductor and earth return when one phase is accidentally earthed.

Item (a) affects the design and construction of the line and its normal operation, while item (b) is the principal factor in determining the magnitude of the "failure" current returning through the earth (under fault conditions) upon which the amount of interference with communication circuits is dependent.

Transposition makes the power lines electrically balanced, equalizes the phase impedances and reduces the induction from normal operating currents and voltages. On single circuit lines transposition entails practically no additional cost and ought to be adopted as standard in all cases. On double circuit lines, however, special "transposition towers" (costing in the case of the "grid" lines several hundred pounds extra per tower) have to be employed at each transposition point (to prevent the conductors touching in the span), and this factor renders it desirable to avoid transposition whenever practicable. On long lines (fed entirely from one end) transposition appears essential both on account of inductive interference and to avoid large differences between the phase impedances.

On short lines (say up to 50 miles long, which covers most practical cases in this country), the latter effect is negligible compared with the transformer impedances, and transposition is unnecessary when, *in addition, interference with communication circuits arising from normal operating currents and voltages is unimportant.* Thus on short double circuit lines no general recommendation regarding transposition can be made and each case must be judged on its merits.

On all double circuit lines, *whether transposed or not*, the time-phase sequence of the conductor currents in the two circuits must be co-ordinated to obtain the best results from the standpoint of operation of the system.

For transposed lines the maximum reduction in phase impedance occurs when the top conductor of each circuit conveys a current of the same time phase as the bottom conductor of the other, the two circuits being transposed at the same frequency and in the same direction of spiral. This gives a small reduction in phase impedance (3 per cent for the "grid" lines) compared with that of a single circuit at similar spacings, but allows a small interchange of power (by transformer action) between the circuits which, however, is negligible in most practical cases (0·28 kW per mile at 220 amperes on the "grid" system).[*]

For non-transposed lines there are two practicable current sequences. In the first method, which gives minimum phase impedance, the current sequence is the same as that given above for transposed circuits. In the second method, conductors in the same horizontal plane convey currents of the same time phase and have equal impedances, thus giving equality of loading of the two circuits when operated in parallel. The ultimate choice depends on the magnitudes of the power transference between the circuits, the phase impedances and the differences between them. These in turn depend upon the particular conductor spacings, etc., employed, but a few simple calculations by the formulæ herein soon indicate which is the better method in a given case. For the "grid" lines the same phase sequence already given for transposed circuits is recommended.

As regards *power losses*, the effects of transposition are negligible except on "long" lines fed entirely from one end, a condition which will seldom, if ever, arise in this country.

If one phase is accidentally short circuited to earth the interference caused to communication circuits is proportional to the magnitude of the current returning through the earth. The percentage of the total short-circuit current returning in this way may be reduced by the employment of an earth conductor bonded to the towers, which provides an alternative path for part of the failure current. The principal *design* factors affecting the reduction obtained are:—

(a) Impedance of the earth conductor.
(b) Method of "earthing" the earth conductor. ("Multiple" earths.)

The earth current is reduced in magnitude by increasing the cross-sectional area of the earth conductor, but not in proportion, because the impedance of the latter depends on the mutual inductance from the earth and short-circuited phase. For this reason after a certain point it is impracticable for economic reasons further to increase the cross-sectional area as the additional reduction obtained thereby is negligibly small, and a second earth wire in parallel with the first should be employed. For example, making the "earth" conductor on the "grid" lines of the same section as the line conductors, which corresponds to increasing the cross-sectional area of aluminium from 0·114 to 0·285 square inch (i.e. by 115 per cent) only decreases the percentage of failure current carried by the earth from about 66 per cent to 58 per cent (for an earth resistivity of 20 000 ohms per centimetre cube, see Table 6 and Fig. 8), whereas a second wire equal in cross-section to the first and suitably positioned below the phase conductors would give a much greater reduction.

On existing systems the use of an all-steel earth conductor is common practice, primarily for mechanical reasons, but because of the high self-impedance of such conductors the above considerations lead to the condemnation of this method

---

[*] The Papers Committee invite written communications, with a view to publication, on papers printed in the *Journal* without being read at a meeting. Communications (excepting those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

[†] "*Power*" *losses* mean herein the heat losses in the conductors due to the line currents. Losses due to corona and leakage conductance are excluded.

[*] These conclusions in no way modify the well-known advantages of co-ordinating the points of transposition of the power and communication circuits.

in favour of a steel-cored aluminium cable, which combines the advantages of great mechanical strength and high electrical conductivity and protection of the steel from corrosion.

With "multiple" earthing (i.e. earthing the earth conductor at every tower) the percentage of failure current returning via the earth is still further reduced, but the extra reduction is only a few per cent except in the immediate vicinity of the ends of the short-circuited section (see Fig. 9). For most practical purposes (i.e. except when the short-circuited section is very short in length, perhaps one or two kilometres) the effect of "multiple" earths may therefore be ignored. The general adoption of multiple earthing is, however, advocated to ensure the earth conductor being "earthed" close up to a "fault" wherever it occurs on the system; thereby preventing the *whole* short-circuit current passing through the earth for any appreciable distance.

These conclusions are based largely on theoretical and experimental work by the authors.

I. INTRODUCTION.

(A) OBJECT OF REPORT.

The determination of the impedance and power losses of a transmission line is a matter of considerable importance. Under normal operating conditions these factors materially affect the efficiency, operation and loading of the system, while if one phase is accidentally earthed the impedance of a line conductor and earth return wholly or partly determines the amount of interference caused to neighbouring communication circuits.

Under both conditions the losses and impedance are dependent upon a number of dimensional and electrical factors, some of which in turn depend upon the material and construction of the line and earth conductors and the manner in which they are laid.

By a suitable control of the different variables, the regulation of the line may be improved and the interference caused to other interests reduced, and the object of this report is to show how this may be done.

(B) SCOPE OF REPORT.

A large amount of information has been published on the impedance of, and losses in, overhead line conductors under normal working conditions, and the general theory underlying the pre-determination in a given case is well understood and supported by experimental evidence. There are, however, certain aspects of the problem which appear to have been inadequately dealt with [*] and at least one aspect upon which current opinion is in error.[†] For this reason a general theory is given in Appendix II which covers all cases likely to arise in practice.

The problem of the impedance of a line conductor and earth return (which arises under short-circuit conditions) has not in the past been completely investigated. Two cases have to be considered, namely, with earth return alone and with an earth conductor bonded to the towers in parallel with the earth path. The case when no earth conductor is employed has been investigated theoretically by Breisig, Mayr, Rüdenberg, Carson [‡] and Pollaczek, but no experimental evidence appears to have been published.

The present authors have recently carried out tests[§] on the 33-kV Runcorn–Ellesmere Port Line of the Mersey Power Company, and the results obtained are

[*] For example, published data on the effects of mutual inductance between the six conductors of a double circuit line only deal with particular time sequences of conductor currents, and no general treatment has previously been given.

[†] See, losses in long line at unity power factor, Section III.

[‡] From private sources of information the authors understand that tests carried out in America substantially confirm Carson's theory.

[§] These tests were made for the Central Electricity Board and carried out in co-operation with the Post Office.

in good agreement with Rüdenberg's method and also on the Bedford–Little Barford "grid" lines. The case when an earth wire is employed has not previously been dealt with, but the authors have extended the theory based on Rüdenberg's assumptions to include this case and have confirmed their results experimentally. The theory for both the above cases is given in Appendix III, together with a comparison of the theoretical and experimental results obtained.

(C) WORKING FORMULÆ.

Working formulæ are given in Appendix IV. Numerical examples are worked out for some typical cases employing the dimensions of the conductors and towers of the 132-kV "grid" system.

II. IMPEDANCE OF A LINE CONDUCTOR WITHOUT EARTH RETURN.

(A) INTRODUCTION.

On a three-phase system[*] the line currents set up a magnetic field around the axis of the conductors. This magnetic field gives rise to a reactance voltage along the lines, and in this way the phase impedance becomes dependent on the line currents and the configuration and spacing of the conductors.

The factors on which the impedance depends are as follows:—

(i) Configuration of the conductor.
(ii) Axial separation of conductors.
(iii) Time-phase sequence of conductor currents.
(iv) Transposition.
(v) Mutual inductance from near-by circuits.

The impedance also depends on the material, stranding and dimensions of the conductors, but this aspect will be considered separately later in the report.

In discussing the impedance voltage-drop along a line it is necessary to take account of the length of line concerned.

The impedance voltage-drop may be defined as the vector difference between the sending and receiving end voltages. It is well known that this is not the same numerically as the product of the receiving-end current and the line impedance because, owing to the effects of capacity and leakage conductance, the magnitude of the current and the impedance voltage-drop per unit length vary all along the line. For a well-maintained line worked well below the corona limit, the effects of leakage conductance may be neglected, and in such cases the error introduced in the estimation of the impedance voltage-drop by ignoring the line capacitance is usually negligible on lines up to about 50 miles long, under practical load conditions. This is shown for the "grid" system by the figures in Table 1. It will be seen that at full load current[*] (220 amperes per phase R.M.S.) the errors introduced by this assumption at 80 per cent power-factor lagging at the receiving end are 2·7 per cent and 6·0 per cent for lines 50 and 100 miles long respectively, while at unity power factor the corresponding figures are 0·23 per cent and 1·8 per cent. At half full load the error on a 50-mile length is about 5 per cent at 80 per cent power-factor lagging.

TABLE 1.

Comparison of Exact and Approximate Values of Impedance Voltage-Drops and Power Losses on the Single-Circuit "Grid" Lines at Full-Load Current (220 Amperes per Phase R.M.S.).

Length of line, miles	Power factor at receiving end	Impedance-drop in line, volts		$\frac{\text{Col. 3}-\text{Col. 4}}{\text{Col. 3}}\times 100$	Power losses, watts		$\frac{\text{Col. 5}-\text{Col. 6}}{\text{Col. 5}}\times 100$
		Exact value	Value neglecting capacitance of line		Exact value	Value neglecting capacitance of line	
50	80 per cent lagging	7 590	7 800	− 2·7	$0\cdot572 \times 10^6$	$0\cdot607 \times 10^6$	− 6·3
100		14 710	15 600	− 6·0	1·11	1·21	− 9·8
200		28 070	31 190	− 11·1	1·99	2·43	− 22·4
500		57 420	77 980	− 35·9	3·82	6·07	− 58·9
50	100 per cent	7 780	7 800	− 0·23	0·607	0·607	0
100		15 530	15 600	− 0·42	1·21	1·21	0
200		30 970	31 190	− 0·72	2·43	2·43	0
500		75 010	77 980	− 4·0	5·99	6·07	− 1·4
50	80 per cent leading	7 980	7 800	2·3	0·643	0·607	5·5
100		16 250	15 600	4·0	1·32	1·21	8·2
200		33 600	31 190	7·2	2·84	2·43	14·5
500		88 920	77 980	12·2	8·16	6·07	34·4

This degree of accuracy is probably greater than that to which the fundamental constants of resistance and inductance of the conductors, upon which the impedance voltage depends, are known. It is doubtful if lines longer than about 50 miles fed entirely from one end will occur in this country, and for this reason attention is mainly directed in this report to the characteristics of such "short" lines in which the effects of capacitance have been neglected.

---

[*] A balanced three-phase system is assumed unless otherwise stated, i.e. one in which the vector sum of the three currents is zero and their time phases are spaced 120° apart.

[*] By "full load current" is meant "full load current at *unity power factor at the receiving end of the line*" unless otherwise stated.

(B) SINGLE CIRCUIT TOWERS.

(i) *Without transposition.*

(*a*) *Short and long lines.*—With asymmetrical spacing of conductors, a three-phase transmission line is not electrically balanced without transposition, and the impedance and admittance per unit length vary at different places. For long lines, in which the effects of capacitance cannot be disregarded, the estimation of the impedance voltage-drop therefore presents some difficulty. No solutions of the problem have been published, although a theoretical solution is obtainable if required. In practice, regular transposition is adopted on all long lines primarily from the standpoint of inductive interference, so that a solution for the untransposed case has no practical utility and has not, therefore, been attempted. The following discussion of untransposed lines has consequently been restricted to short lines, which cover practical requirements in this country.

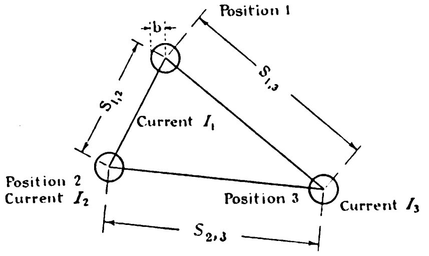

FIG. 1.—Asymmetrical arrangement of conductors on single circuit tower.

(*b*) *Configuration and axial separation* (*short lines*).—When the three conductors are spaced asymmetrically (see Fig. 1) and are not transposed, the impedances are different in all three phases. At practical spacings of conductors the reactance of any phase is approximately proportional to the logarithm of the product of the axial distances from that phase to each of the other two. Thus the amounts by which the reactances of the three phases differ is dependent on the degree of asymmetry of the conductors, but in practical cases the inequality in the reactances is not very great. On the single circuit towers* of the "grid" system, the three reactance values (see Table 2) are 0·654, 0·660 and 0·686 ohm/mile to neutral,† giving a total variation of only 5 per cent, although the distances between the axes of the three conductors are 377, 636 and 724 cm, i.e. have a maximum variation of over 90 per cent.

The effect of asymmetrical spacing in the phase resistance is much greater. This factor causes an interchange of power between the phases through the magnetic field, which makes the apparent resistance‡ of a conductor different from its a.c. resistance.* A measure of the power transferred to or from any phase is the product of the absolute value of the current and the difference between a.c. and apparent resistances. If this product is negative then the phase considered is transferring power to the other phases and *vice versa*.

On the single circuit towers of the "grid" lines (see Table 2), the power transferred is + 2·23 kW, − 2·76 kW and + 0·53 kW per mile for the three phases for the conditions shown in Fig. 1, at an assumed current of 220 amperes per phase. Obviously these three quantities sum up to zero.

The apparent resistance thus only affects the impedance voltage-drops and not the power loss which is the same in all phases and is equal to the square of the absolute (or measured) value of the current multiplied by the a.c. resistance. In practical cases the differences thus caused in the apparent resistances may be considerable. On the "grid" system the a.c. resistance of the conductors is 0·251 ohm/mile at 60° F., but two of the phases have apparent resistances about 20 per cent above and below this value (see Table 2).

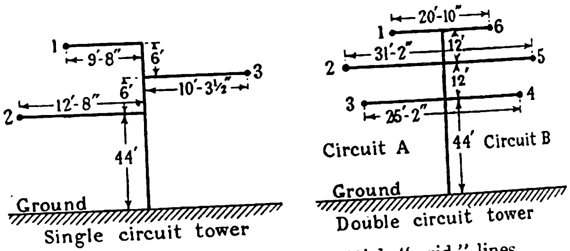

FIG. 2.—Dimensions of Scottish "grid" lines.

$S_{1,2} = 12\cdot37' = 377$ cm
$S_{1,3} = 20\cdot84' = 636$ cm
$S_{2,3} = 23\cdot73' = 724$ cm

$S_{1,2} = 13\cdot06' = 398$ cm
$S_{1,3} = 24\cdot09' = 735$ cm
$S_{1,4} = 33\cdot24' = 1\,013$ cm
$S_{1,5} = 28\cdot64' = 875$ cm

$S_{1,6} = 20\cdot83' = 636$ cm
$S_{2,3} = 12\cdot37' = 377$ cm
$S_{2,4} = 30\cdot62' = 935$ cm
$S_{2,5} = 31\cdot17' = 951$ cm
$S_{3,4} = 25\cdot17' = 774$ cm

Note.—Maximum sag of line conductor at centre of span is 21′ 6″.

Line conductor; constants and dimensions.
Stranding = 30/0·110″ diameter. Aluminium on 7/0·110″ diameter steel.
A.C. resistance = 0·251 ohm/mile at 60° F. External diameter = 0·77″ (1·955 cm).

Earth conductor; constants and dimensions.
Stranding = 12/0·110″ diameter. Aluminium on steel core, 7/0·110″ diameter.
External diameter = 0·55″ (1·397 cm).
Assume a.c. resistance of isolated earth conductor at 50 ~ = 0·629 ohm/mile at 60° F.

(*c*) *Time-phase sequence of conductor currents.*—The time-phase sequence of the conductor currents for a given spatial configuration, does not affect the phase reactance, but the effect on the apparent resistance and the impedance is important. For a single three-phase circuit there are only two possible ways of permuting the phase sequence of currents, namely, the sequences 1, 2, 3, and 1, 3, 2, and investigation shows that the direction of the power transference is opposite in the two cases (see Table 2). If for the former sequence the apparent resistance of any phase exceeds the a.c. resistance by a given amount, then for the latter sequence the apparent resistance will be less than the a.c. resistance by the same amount. For a given phase sequence the inequality of the apparent resistances makes the impedances unequal, but usually to a less degree in practical cases. For the "grid" lines the total variation in apparent impedance is only about 6–7 per cent, though the apparent resistances differ by nearly 50 per cent.

---

* See Fig. 2 for dimensions of towers, etc.

† All reactances quoted are at 50 cycles unless otherwise stated.

‡ The numerical values of the apparent resistance and reactance of a conductor are the values obtained by dividing the voltage drops along the conductor which are respectively in phase with and in quadrature with the line current, by the R.M.S. value of the current.

* The a.c. resistance of a conductor means herein the a.c. resistance of an *isolated* conductor under the conditions assumed. For non-magnetic conductors this is, for practical purposes, equal to the d.c. resistance, but for steel or steel-cored conductors a material difference may exist depending on the stranding, chemical composition and current density.

(ii) *With transposition* (*short and long lines*).

Regular transposition causes the interchange of power between the conductors to balance out in any phase over an integral multiple of three transpositions and makes the line electrically balanced.

TABLE 2.

Single Circuit Tower Line Constants of "Grid" System.

Configuration	Phase sequence of currents	Regular trans-position	Apparent resistance (ohm/mile)		Apparent reactance to neutral at 50~ (ohm/mile)		Apparent impedance to neutral at 50~ (ohm/mile)		Power trans-ferred to or from the phase per mile*
			Phase		Phase		Phase		kW
Asymmetrical triangular (grid system)	 $I_2 = I_1 e^{2\pi j/3}$ $I_3 = I_1 e^{4\pi j/3}$	Not†	1 2 3	0·205 0·308 0·240	1 2 3	0·654 0·660 0·686	1 2 3	0·685 0·728 0·727	+ 2·23 − 2·76 + 0·53
Asymmetrical triangular (grid system)		Not†	1 2 3	0·297 0·194 0·263	1 2 3	0·654 0·660 0·686	1 2 3	0·718 0·688 0·735	− 2·23 + 2·76 − 0·53
Asymmetrical triangular (grid system)	Any	Yes	0·251		0·667		0·711		Zero

Under such conditions the impedances of all phases are equal,‡ the apparent resistance being the same as the a.c. resistance of an isolated cable and the reactance the average of the values for the three conductor positions.

(C) DOUBLE CIRCUIT TOWERS.

(i) *Introduction.*

When two three-phase circuits are carried on the same transmission tower, the phase impedance depends on the same dimensional and electrical factors as a single circuit and, in addition, on the mutual inductance between the two circuits. In the following discussion it will be assumed (unless otherwise stated) that the two circuits are symmetrically spaced about the vertical centre line of the tower, are separately balanced and carry equal loads, which is the usual practical case.

(ii) *Phase impedance without transposition* (*short lines*).

The mutual inductance between the two circuits depends upon the time phase sequence of the conductor currents, and when neither circuit is transposed the effects are rather complicated. For any given spatial configuration and axial separation of the conductors, if the time sequence in one circuit is kept fixed, there are 6 possible ways of permuting the currents in the other circuit (see Figs. 3 (*a*), (*b*), (*c*), (*d*), (*e*), (*f*)). There are, however, only 12 possible ways of permuting the currents in *both* circuits (see Figs. 3 (*a*) to 3 (*l*)), since if the time phase of *all* the currents is advanced by any given amount (say, $2\pi/3$ or $4\pi/3$) the impedances are unaltered.

Investigation shows that these 12 arrangements only lead to 36 different impedance equations (i.e. half as many as there are conductor positions) for the following reasons:—

Ten of the arrangements (all except Figs. 3 (*d*) and 3 (*g*)) may be divided into two sets of five in which the $5 \times 6 = 30$ impedance equations are the same for each, the only difference being that in any two corresponding figures (one from each set of 5) the phase impedances of the two circuits are interchanged. Corresponding arrangements are Figs. 3 (*a*) and 3 (*j*), 3 (*b*) and 3 (*k*), 3 (*c*) and 3 (*l*), 3 (*e*) and 3(*f*), 3 (*h*) and 3 (*i*).

For the other two arrangements (viz. 3 (*d*) and 3 (*g*)) the 3 impedances of the two circuits in each figure are equal, thus giving a total of $30 + 6 = 36$ possible impedance equations.

---

* A + sign indicates a power transference to the phase considered from the other phases and *vice versa*. Current assumed is 220 amps. per phase corresponding to 50 000 kVA transmitted three-phase at unity power factor at receiving end of line.

† These values apply to short lines only.

‡ Equality in phase impedance also occurs when the 3 conductors are arranged at the corners of an equilateral triangle, but this construction is not often employed in practice.

In the general case where the conductors of each circuit are asymmetrically spaced, the numerical value of the impedances may be greater or less than that of a single circuit at similar spacings according to the phase sequence selected. At practical conductor spacings the apparent reactance in any arrangement * is approximately proportional to the logarithm of the product of the axial distances from the conductor considered to the other four carrying current of different time phase, minus twice the logarithm of the product of the radius of the conductor and the axial distance between it and the conductor carrying current of the same time phase. Since there are only *three* possible values for the latter dimension for any given conductor (conductors having currents of the same time phase being in different circuits), there are only three possible reactance values for any given conductor position (in all 12 current permutations) and only *nine* different reactances for *all* the 36 impedance equations.

The apparent resistance is equal to the a.c. resistance of an isolated conductor plus a term (due to power transference between the conductors and which may be positive or negative in sign) proportional to the logarithm of the product of the axial distances from the conductor considered to the two carrying currents $2\pi/3$ later in

FIG. 3.—Diagrams showing the twelve possible permutations of the time phases of the currents in the conductors of a double circuit tower.

The conductors of each circuit are asymmetrically spaced, but the two circuits are symmetrical about the vertical centre line of the tower.

The left- and right-hand circuits on double circuit lines are termed circuits "A" and "B" respectively in Appendices II and IV.

---

* See Appendix II for mathematical expression.

time phase, minus the logarithm of the product of the axial distances from the conductor to the two carrying current $4\pi/3$ later in phase.

The power transference above mentioned takes place not only between the conductors of each circuit, but between the two circuits. The latter is usually of negligible amount in practical cases and for the "grid" system varies between zero and 2·5 kW per mile at a line current of 220 amperes R.M.S. Each phase receives power from or transmits power to each of the four conductors carrying current having a different time phase from its own. There is, however, no interchange of true power between conductors in which the currents have the same time phase, as the term in the apparent resistance due to power transference does not involve the axial dimension between them, which dimension would be involved if transformer action were occurring. It may be noted that since this dimension does enter into the apparent reactances, there is an interchange of "wattless" power between conductors carrying currents of the same time phase. The heating of the conductors is unaffected by the power transference and is equal in all phases. On single circuit lines the cost of transposition is small and involves no practical difficulties, but on double circuit lines special "transposition" towers have to be employed (at which the lines are cut and the transposition effected by means of "jumpers") in order to avoid difficulties due to the conductors touching in the span. This involves considerable expense (about £250 to £300 extra for each transposition tower on the "grid" lines) and objections have also been raised to these towers on account of unsightliness.

Transposition is customary on long lines to reduce inductive interference and to avoid large differences in the impedance voltage-drops along the different phases, but on short lines the latter effect may be negligible when taken in conjunction with the greater impedance of the transformers, and where a wide separation exists between power and communication circuits the elimination of transpositions may be practicable. For this reason it is important to know which of the twelve possible current permutations is most desirable from the standpoint of operation of the system. The three factors of primary importance are parallel operation of the two circuits, reduction of power transference between the circuits and reduction of phase impedance. For parallel operation the three impedances of the first circuit must be the same as those of the second, otherwise the load will not divide equally between them. This condition is fulfilled only by the arrangements of Figs. 3 (*d*) and 3 (*g*) in which the impedances of phases in the same horizontal plane are equal. An additional advantage is that there is no interchange of power between the circuits under these conditions.

From the standpoint of reduction of impedance the arrangements of Figs. 3 (*c*) and 3 (*l*) are the best and give, in the case of the "grid" lines, values between about 1 per cent and 3 per cent (for the different phases) lower than those of a single circuit. The total variation of impedance between the various phases is about 6 per cent [compared with about 15 per cent for Figs. 3 (*d*) or 3 (*g*)], while the maximum variation in the apparent resistances is plus or minus 17 per cent of the a.c. resistance (see Table 3). Figs. 3 (*c*) and 3 (*l*) are also favourable from the aspect of power transference between the two circuits, the amount for the "grid" system being only 0·28 kW per mile at a line current of 220 amperes, which is less than for any other arrangement except Figs. 3 (*d*) and 3 (*g*).

(iii) *Effects of transposition* (*short and long lines*).

(*a*) *Foreword.*—From a practical standpoint, transposition is of great importance and in dealing with its effects two cases have to be considered, namely, with the frequencies of transposition in the two circuits equal and unequal.

(*b*) *Circuits transposed at same frequency.*—Regular transposition makes the impedance the same in all three phases of each circuit over an integral multiple of three transpositions, *provided the two circuits are transposed in such directions as to maintain the same relative positions of conductors carrying currents of the same time phase.*

The impedance in a given case is the average of the three values applying to the separate phases of the circuit when not transposed. Since for any given spatial configuration and axial separation there are 36 different impedance equations for the 12 permutations of conductor currents *without* transposition, it follows that there cannot be more than $36/3 = 12$ different equations *with* transposition. Actually there are only eleven (see equations 15 (*a*)–(*g*), Appendix II) because in Figs. 3 (*d*) and 3 (*g*) owing to the disappearance of the power transference between the circuits, the impedances of all four circuits are the same. For the remaining 10 arrangements (i.e. all except Figs. 3 (*d*) and 3 (*g*)), the 10 impedances of one half (viz. 5 arrangements) equal those of the other half, corresponding arrangements in the two halves having their impedance equations interchanged. The impedance equations for the 12 possible current permutations (involving six different reactances and nine resistances) fall naturally into three groups as under:—

Group 1: Figs. 3 (*a*), 3 (*b*), 3 (*c*), 3 (*j*), 3 (*k*), 3 (*l*).
Group 2: Figs. 3 (*d*) and 3 (*g*).
Group 3: Figs. 3 (*e*), 3 (*h*), 3 (*f*), 3 (*i*)

In the *first group* the apparent reactances of the two circuits in any arrangement are equal, while the terms in their apparent resistances due to power transference are numerically equal and of opposite sign. There is also an interchange of power between the two circuits in each arrangement.

In the two arrangements forming the *second group*, the resistances, reactances and impedances of all four circuits are equal. There is no power transference between the circuits in either arrangement.

In the *third group* the apparent reactances of the two circuits in any arrangement are unequal. The terms in the apparent resistances due to power transference are numerically equal and of opposite sign, and there is a power interchange between the two circuits.

The chief practical aspects of transposed circuits are the same as for the non-transposed case, namely, reduction of impedance, elimination of power transference and parallel operation of the circuits. Since the arrange-

* A + sign indicates a power transference to the phase considered from the other phases and *vice versa*. Current assumed is 220 amps. per phase corresponding to 50 000 kVA transmitted three-phase at unity power factor at receiving end of line.

† These values apply to short lines only.

ments of Figs. 3 (*d*) and 3 (*g*) are the only ones in which the two circuits have equal impedances when transposed at the same frequency,[*] strictly speaking these are the only cases in which the load will divide equally with parallel operation, but at practical conductor spacings the inequalities arising from this cause in *any* of the arrangements are usually negligible. On the "grid" lines the impedance in the above two cases is about 2 per cent greater than for a single circuit at similar spacings (see Table 3). Respecting reduction of impedance, clearly this reduction will be greatest for the same arrangements as when the conductors are not transposed, viz. Figs. 3 (*c*) and 3 (*l*). For these arrangements the impedance for the "grid" system is about 3 per cent less than that of a single circuit at similar spacings, while the power transference between the circuits is only 0·28 kW per mile and, therefore, of no importance.

(*c*) *Circuits transposed at different frequencies.*—There is only one important case, namely, when the frequencies of transposition in the two circuits are in the ratio 3 : 1. Under such conditions the effects of mutual inductance between the circuits balance out over an integral multiple of three transpositions of the circuit having the lower frequency of transposition. The line constants are then the same in all six phases and equal to that of a single transposed circuit at similar spacings, irrespective of the phase sequence of conductor currents. For practical cases this method of transposition has no advantages over those of Figs. 3 (*d*) and 3 (*g*) and is inferior to those of Figs. 3 (*c*) and 3 (*l*), when the frequency of transposition in the two circuits is the same.

(D) CONSTRUCTION OF CONDUCTOR.

The construction of a conductor affects both its resistance and reactance. In non-magnetic conductors the only important effect is that due to stranding which increases the resistance by one or two per cent and decreases the reactance by a like amount at close conductor spacings, i.e. a few feet. At the wide spacings commonly used on high-voltage lines (such as the "grid" system) the effect of stranding on the reactance is only a fraction of one per cent, and for practical purposes may be ignored. In aluminium conductors with steel cores the spiralling of the strands produces an axial field which tends to increase the self-inductance, but the higher resistivity of the steel reduces the current density in the core and thus the linkages and the two effects partly or wholly neutralize. With only one layer of aluminium over the steel the solenoid effect is the greater, and a net increase of inductance results which may reach 17 per cent, depending on the current density. With two or more layers spiralled in opposite directions the reverse is the case, and a net decrease of about 5 per cent at three-feet spacing occurs compared with the inductance of a non-magnetic conductor of similar stranding and overall diameter. The extra cross-section afforded by the steel tends to reduce the resistance by 1 per cent or 2 per cent, but the hysteresis and eddy-current loss set up in the steel by the axial field above mentioned may increase the loss by many times this amount, depending on the frequency and current density. With a single layer of aluminium, the a.c. resistance at high-current densities may be 25 per cent greater than at low values, while for three-layer conductors the increase may be 20 per cent. For double-layer conductors, the increase is negligible and the a.c. resistance may be taken as equal to the d.c. resistance (at commercial frequencies and current densities).[*]

III. POWER LOSSES (SHORT AND LONG LINES).

On a short line the sending and receiving end currents are substantially equal in magnitude. The power loss is then equal to the product of the square of the (R.M.S.) line current and the a.c. resistance (of an isolated conductor), and is thus directly proportional to the length of line and independent of transposition, line voltage, power factor, etc.[†] On long lines regularly transposed (which is the only practical case) the losses are no longer directly proportional to the length of the line, but depend in a complicated way on the resistance, impedance and admittance per unit length, the load current and the receiving-end power factor and voltage. It is usual in such instances to determine the power losses as the difference between the power at the sending and receiving ends,[‡] but this is an indirect and not very accurate method and the authors have, therefore, developed a single expression from which the losses may be determined directly[§] from the receiving-end conditions and length of line, etc.

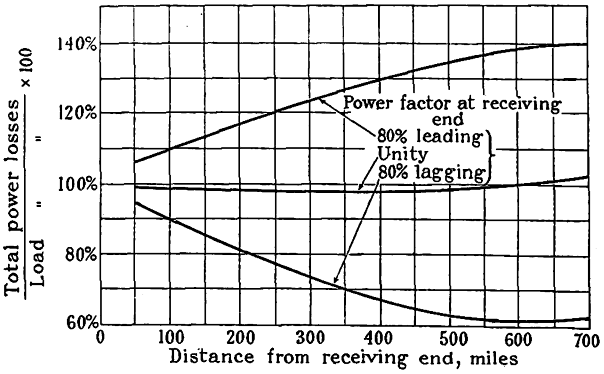

FIG. 4.—Curves showing the relation between the ratio (Power losses)/(Load power losses) and distance from receiving end of line at full load current 220 amps. for "grid" lines.

---

[*] It may be noted that for the sequence of Figs. 3 (*d*) and 3 (*g*) the two circuits in either arrangement are transposed in opposite directions of spiral, while for Figs. 3 (*c*) and 3 (*l*) the directions are the same.

[*] In some agricultural districts galvanized steel conductors have been used for the transmission of small amounts of power. For such conductors, hysteresis and eddy-current losses greatly increase the ratio of

$$\frac{\text{a.c. resistance}}{\text{d.c. resistance}}$$

while the non-uniform current distribution over the cross-section makes the internal reactance (which is usually negligible in non-magnetic conductors) greater than the external reactance, at practical spacings. These constants moreover vary widely according to the chemical composition and must be determined experimentally. See WALTON, Bib. Ref. No. 34, for typical figures.

[†] The error in estimating the losses at full load on the "grid" system for a line 50 miles long due to neglecting capacitance is substantially zero at unity power factor and about 6 per cent for 0·8 leading or lagging. For a line 100 miles long the errors are zero and about 9·5 per cent respectively. See Table 1 and Fig. 4. At one-half full load the percentage error on a 50-mile line is about 12 per cent at 0·8 power factor lagging.

[‡] Assuming the leakage conductance to be zero.

[§] See Appendix II, equation (21).

The capacity current may increase or decrease the "load" losses (i.e. the losses due to the load current alone) depending on the power factor at the receiving end and length of line.

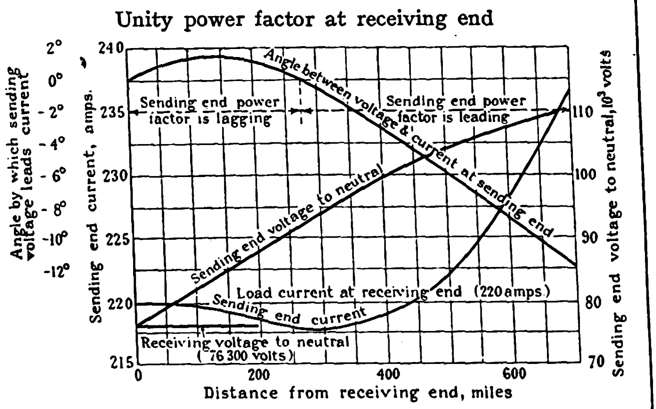

FIG. 5.—Curves showing the variation in magnitude of the sending-end current and voltage, and in the angle between the latter quantities, with distance from the receiving end for the "grid" system at full-load current 220 amperes at receiving end. (Receiving voltage to neutral maintained constant at 76 300 volts.)

If the power factor is lagging the charging current neutralizes part of the lagging component and thus decreases the absolute value of the current at a given point, upon which the losses depend. As the length of line increases, the percentage reduction increases up to a certain length, after which there is a rise again.* By similar reasoning the losses for a leading power factor at the receiving end are always greater than the load losses alone.

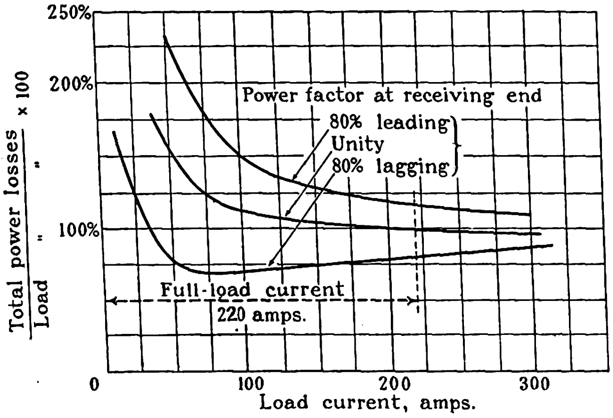

FIG. 6.—Curves connecting $\frac{\text{Power losses}}{\text{Load power losses}}$ with load current for "grid" lines on a length of 200 miles.

At unity power factor it is usually stated † that the losses are necessarily increased, but this is incorrect. Investigation shows that on the "grid" lines the absolute value of the sending-end current decreases slightly (at full load) as the distance from the receiving end increases from 0 to 300 miles, where the current has a minimum value. The current then rises again until the sending- and receiving-end currents are equal at a line length of 440 miles, after which the sending-end current rises rapidly with increasing length of line (see Fig. 5).

For this reason the full load losses at unity power factor are *less* than the losses due to the load current alone for any length of line up to about 620 miles (see Fig. 4).

The line losses are increased by raising the line voltage, but not in proportion. In the above example on a 500-mile line raising the line voltage from 132 kV to 220 kV increases the full load losses by 11 per cent, 32 per cent and 40 per cent for receiving-end power factors of 0·8 lagging, unity and 0·8 leading respectively.

In most cases arising in this country the error introduced in the losses by neglecting the line capacitance, will be less (except at very light loads, see Fig. 6) than that with which the fundamental constants of line resistance and reactance are known.

IV. IMPEDANCE OF A LINE CONDUCTOR AND EARTH RETURN.

(A) INTRODUCTION.

On a three-phase transmission line the magnitude of the short-circuit current flowing when one phase is accidentally earthed, depends wholly or in part on the impedance of the earthed phase and earth return.

Two practical cases arise in which the effects are materially different, namely, with and without an earth conductor bonded to the towers. The principal functions of the earth conductor are as follows:—

(*a*) A protection against lightning discharges.
(*b*) A protection against the results of mechanical failure of the live conductors.
(*c*) A means of reducing inductive interference in communication circuits.

For the requirements of electrical protection a conductor of relatively small cross-sectional area would suffice, but should a mechanical failure of a line conductor occur the mechanical stresses would have to be transmitted to adjacent towers, and this factor determines the mechanical strength required.

The reduction obtained in inductive interference depends upon the percentage of the short-circuit current in the earthed phase which can be shunted through the earth conductor back to the supply. This is to some extent a matter of the relative impedances of the earth and earth conductor, so that it is advantageous for the latter to have a low impedance.

In the past only the first two of the three above-mentioned uses of an earth conductor appear to have been fully recognized, and the dimensions of the conductor have been based on considerations of mechanical strength alone. This has resulted in the frequent use of steel earth conductors, a construction which, as we shall show, is disadvantageous from the standpoint of interference.

---

* At 0·8 power factor lagging the ratio of the $\frac{\text{Total losses}}{\text{Load losses}}$ is a minimum on the grid lines at a line length of 650 miles (see Fig. 4).

† E.g. NESBIT: Bib. Ref. No. 1.

(B) IMPEDANCE WITHOUT EARTH CONDUCTOR.

When no earth conductor is employed the impedance of the line and earth depends upon the following factors:

(*a*) Conductivity and dimensions of the line conductor.
(*b*) Supply frequency.
(*c*) Electrical resistivity of the earth.
(*d*) Impedance of earth plates and fault connection.

(*a*) and (*b*) are determined by considerations outside the present scope and are thus, in this instance, not controllable factors. It may be noted, however, that the impedance is reduced by decreasing the resistance of the line conductor and/or increasing its overall diameter. Increase of frequency increases both resistance and reactance and on the grid system the impedance is roughly proportional to frequency. For example (assuming an earth resistivity of 20 000 ohms/centimetre cube) the impedance values are 1·25 ohms/mile and 0·69 ohm/mile at 50 cycles and 25 cycles respectively (see Table 4). The effect of increasing the earth resistivity is to increase the reactance and thus the impedance, but the effects are small in practice. In the case last quoted a variation in resistivity from 500 ohms/centimetre cube to 20 000 ohms/centimetre cube, which covers most practical cases, only causes a variation in impedance from 1·07 to 1·25 ohms/mile at 50 cycles (see Table 4). The impedance will also obviously increase with increase in resistance of the earth plates and fault connections. In practice this factor may be neglected as this leads to an over-estimate of the fault current and its inductive effects, which is an error on the safe side. It may, however, readily be taken into account, if desired, in instances where the values are known.

TABLE 4.

Effect of Resistivity of Earth and Supply Frequency on Impedance of Line Conductor and Earth Return.

Single Circuit Towers "Grid" System.

Earth resistivity, ohms per cm cube	Impedance in ohms per mile of line conductor and earth					
	Without earth wire in parallel with earth			With earth wire in parallel with earth		
	50 ~	40 ~	25 ~	50 ~	40 ~	25 ~
20 000	1·25	1·02	0·688	1·06	0·894	0·638
10 000	1·22	0·995	0·672	1·05	0·880	0·628
5 000	1·18	0·969	0·654	1·03	0·865	0·614
1 000	1·10	0·908	0·620	0·993	0·832	0·590
500	1·07	0·883	0·602	0·975	0·820	0·573

The above figures refer to a short-circuit to earth on the middle phase of a single circuit tower on the Scottish grid lines. See Fig. 2 for dimensions of towers and line and earth conductors.

It is interesting to note that the impedance is, for all practical purposes, independent of the height above earth of the earthed phase.

(C) IMPEDANCE WITH EARTH CONDUCTOR.

(i) *Introduction.*

When an earth conductor is employed, the impedance of the line conductor and return path (through the earth and earth wire in parallel) depends on the same factors as in the previous case, the effects being in general similar and of the same order of magnitude (see Table 4). In addition, the impedance depends upon the location of the earth conductor and fault phase with respect to each other and the earth, on the impedance of the earth conductor, and on the magnitude of the resistance between the earth wire and earth at each tower. We shall first deal with the case where the earth wire is insulated from earth except at the fault and the generator end of the line (see Fig. 7).

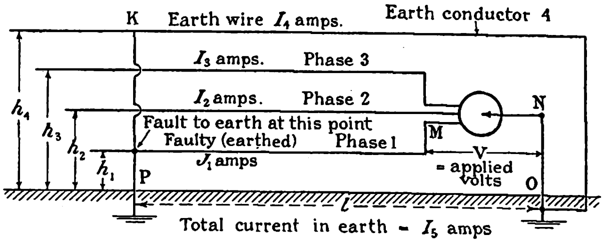

FIG. 7.—Explanatory diagram in connection with the calculation of the impedance of an overhead line with earth return. (See Appendices III and IV (2).)

Total current in earth = I_5 amperes.
Short-circuit current J_1 = earth current + earth wire current = $I_5 + I_4$.

(ii) *Impedance without "multiple" earthing.*

It is usual for the earth conductor to be situated at the top of the tower, and its position and those of the phase conductors are decided upon for mechanical and other reasons outside the present scope. The influence of the location of the earth and line conductors reduces, therefore, in a practical case to a variation of impedance according to which phase is earthed. For a given position of the earth conductor the impedance decreases as the height above earth of the earthed phase increases, but the effect is small and only amounts to 3 per cent for the "grid" lines (see Table 5).* This factor also causes a small variation in the percentage of the short-circuit current which returns via the earth. For the example already quoted this percentage varies 5 per cent between the top and bottom phases (see Table 5).

The impedance of the earth conductor is a factor of much greater importance. The magnitude of the effect depends upon the value of the impedance of the line and earth return compared with that of the rest of the circuit in which the fault occurs. This in turn partly depends on the location along the line at which the phase is earthed.

---

* In the practical example shown in Table 5, the horizontal distances of the three line conductors from the vertical centre line of the pole vary slightly so that there are two variables, but the effects are similar in a theoretical case in which the above-mentioned horizontal distances are equal.

Two extreme cases will be considered as follows:—

(*a*) When the impedance of the line and earth is negligible compared with that of the transformers, etc.

(*b*) When the impedance of the line and earth is the principal impedance.

All other cases lie between these two extremes. Under condition (*a*) above, the magnitude of the short-circuit current in the earthed phase is independent of the impedance of the line and earth and may, therefore, be assumed constant. The percentage of this current returning via the earth which determines the amount of interference, depends on the relative magnitudes of the impedance of the earth conductor and the earth. Interference will obviously be a maximum when the earth conductor has infinite impedance (i.e. is absent), while if the impedance of the earth conductor could be made zero there would be no appreciable interference. These effects are illustrated in the case of the "grid" lines by curve A (Fig. 8) and Table 6. Ordinates to this curve are proportional to the percentage of the total short-circuit current (in the earthed phase) which returns via the earth, and it will be seen that the impedance of the earth conductor exerts a material effect. Point "x" corresponds to the particular size of steel-cored aluminium earth conductor to be employed in this country, and it will be seen that this reduces the interference by about 34 per cent. If the cross-section is increased about 2·5 times (which corresponds to making the earth conductor the same size as the phase conductors) a further reduction of 8 per cent is obtained (point "y"), but further increasing the conductivity of the earth conductor 4·3 times only reduces the interference by another 4 per cent (point "z"). The reason why a given increase in conductivity of the earth wire does not give a proportionate reduction in interference is that the impedance of the latter depends not only on its resistance and self-inductance, but also on the amount of mutual inductance from the earthed phase, and under practical conditions the latter is the controlling factor. Under the other extreme condition, namely (*b*) above, the impedance of line and earth determines the magnitude of the short-circuit current. In this case the percentage of this current shunted via the earth conductor is the same as before (other things being equal), but the net reduction in interference is less because an increase in conductivity of the earth conductor also increases the short-circuit current in the earthed phase. To obtain a measure of the interference it is necessary, therefore, to multiply the percentage of the total short-circuit current which passes through the earth by the ratio of the impedance of the line conductor and earth alone to that of the line conductor, earth and the particular earth wire employed. For the "grid" lines, the result is given by point x', Curve B (Fig. 8) and Table 6, which shows that about 78 per cent of the total current now returns through the earth compared with 66 per cent before.

TABLE 5.

Effect of Height of Conductor on Impedance of Line Conductor and Earth Return (assuming Resistivity of Earth as 10 000 *ohm/cm cube).*

Single Circuit Towers "Grid" Lines.

Approximate mean height of line conductor above earth cm	Impedance at 50 ~ in ohms/mile of line conductor and earth return (earth wire in parallel with earth)	$\frac{\text{Current in earth wire} \times 100}{\text{Total short-circuit current}}$
		Per cent
Top phase, 1 370	1·03	38·8
Middle phase, 1 190	1·05	35·6
Bottom phase, 1 005	1·06	33·2

It is evident that although increasing the conductivity of the earth wire always decreases the amount of interference, yet a limit in dimensions is soon set by economic considerations.

For these reasons, to obtain further reduction in interference on the "grid" lines it would be more economical to employ 2 earth conductors in parallel one above and the other below the phase conductors, the second being, say, of the same cross-section as the present earth wire, as this would reduce the interference by perhaps 55 per cent compared with a total reduction of about 46 per cent if the cross-section of aluminium of the present single earth conductor wire were increased even *10·5 times*.

For any given set of conditions (i.e. line voltage, spacing and height of conductors, etc.) there would be an optimum position for the second earth wire to give maximum reduction in interference, which position could readily be calculated by the present methods. The ultimate choice of position would, however, also have to take into consideration other variables such as cost, possible dangers from flash-overs due to swaying of wires, ground clearance, etc. Up to the present, no instances of this kind have arisen in this country.

The figures given above are based on an assumed earth resistivity of 20 000 ohms/centimetre cube, and to cover the range of 20 000–500 ohms which includes most practical cases, curves C and D have been drawn in a similar way to A and B respectively, but for 500 ohms/centimetre cube, which increases the percentage current returning through the earth in a given case. It may be said that the percentage of short-circuit current carried by the "earth" conductor on the "grid" system may vary in practice between about 18 per cent and 34 per cent, depending on the earth resistivity and the impedance of the transformers, etc., connected to the line.

(iii) *Effect of "multiple" earths.*

The fact that the earth conductor is connected to earth at each tower introduces some additional features.

The authors' tests on the Bedford–Little Barford section (9 miles long) of the "grid" lines show that under usual conditions the effect of these intermediate earths is to cause a large current to flow in the earth conductor (as much as 70–90 per cent of the total short-circuit current) at the ends of the section of the line under short-circuit. As the centre of the section is approached this current decreases rapidly to the value which would be obtained were the intermediate earths absent (see Fig. 9). Under usual conditions this effect does not reduce the interference compared with the case previously considered by more than a few per cent and may from a practical standpoint be ignored.

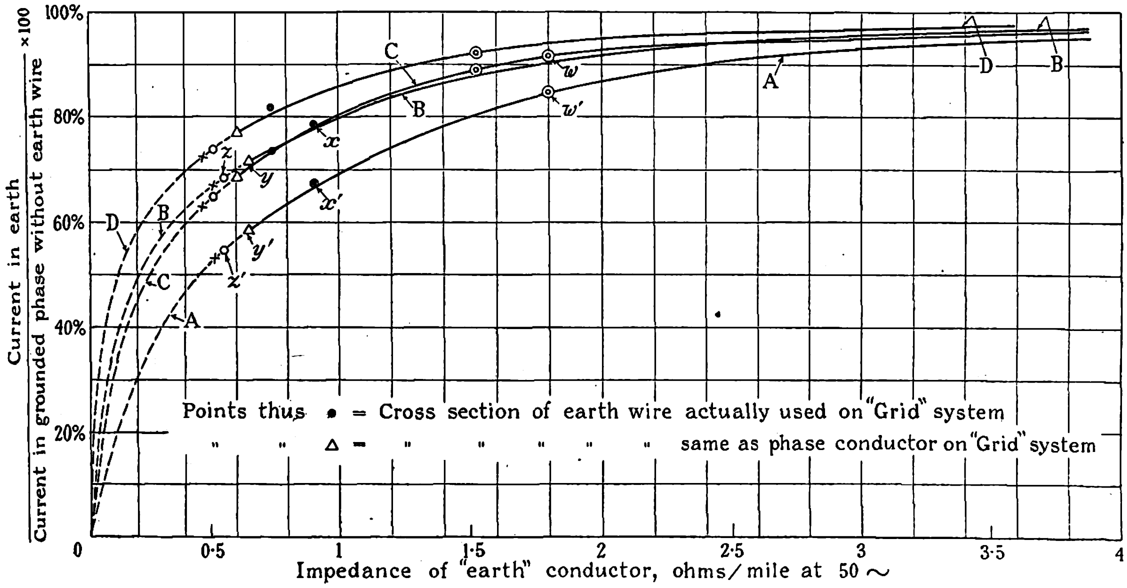

FIG. 8.—Curves showing how the percentage of total short-circuit current passing through the earth under fault conditions varies with the impedance of the earth conductor employed. (For explanation of points, see Table 6.)

For curves A and C.—It is assumed that the impedance of the line conductor and return path via the earth and earth wire in parallel is negligible compared with the impedance of the transformers, etc.

For curves B and D.—It is assumed that the impedance of the line conductor and return path via the earth and earth wire in parallel is the principal circuit impedance.

TABLE 6.

Explanatory Table for Fig. 8.

Dimensions of earth wire			Curves A and B Earth resistivity=20 000 ohms per cm cube			Curves C and D Earth resistivity=500 ohms per cm cube			Notation of point
Stranding		Aluminium section, sq. in.	Impedance in ohms/mile at 50 ∼	Earth current / Total current per cent		Impedance in ohms/mile at 50 ∼	Earth current / Total current per cent		
Aluminium	Steel			A	B		C	D	
120/·170	7/·170	2·66	0·514	52·4	66·9	0·475	62·5	72·4	×
54/·170	7/·170	1·20	0·557	54·4	68·9	0·522	64·3	74·0	o
30/·110	7/·110	0·279	0·644	58	71·2	0·610	67·6	76·6	Δ
12/·110	7/·110	0·114	0·906	66·5	78·4	0·762	74·4	81·7	·
6/·0935	1/·0935	0·0404	1·8	84·6	90·5	1·53	88·6	92·2	⊙
6/·059	1/·059	0·0164	3·84	95·7	97	3·54	96·5	97·5	(See footnote *)

Points thus · = cross-section of earth wire actually used on "grid" system.
Points thus Δ = cross-section of earth wire same as phase conductor in "grid" system.

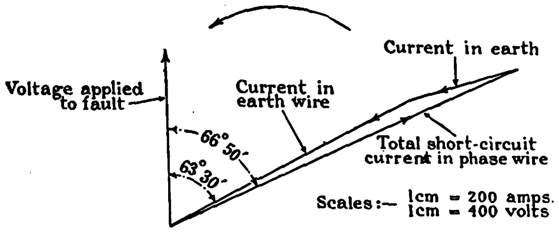
[*] To avoid confusion the notation points have been omitted from the curves.

The magnitude of the effect depends chiefly upon the effective "earth plate" resistance at the fault and end of the line, and the manner in which the earth conductor is in electrical connection with the return path of the current. In Appendix III some formulæ † are given for the case where the fault occurs at a tower, that is the earth conductor is directly connected to the return path of the current, while the earth current proper must flow through the earth plate resistance at the fault tower.

---

† These formulæ are in close agreement with the authors' tests above mentioned.

It is clear, however, that a general treatment is difficult owing to the number of ways in which a fault may occur. Fortunately, however, as already mentioned, the effect is not usually of great importance even in the case treated herein mathematically, which should give a large effect. With very short lines of a few kilometres or in the case of a fault close to a generating station the effect may indeed be large. Accordingly, it is desirable that the earth conductor should be capable of carrying the majority of the short-circuit current in order to avoid failure should such conditions arise.



Voltage applied to fault
Current in earth wire
Current in earth
66°50'
63°30'
Total short-circuit current in phase wire
Scales:— 1cm = 200 amps. 1cm = 400 volts

Vector diagram of observed currents and voltages at point X on curve below

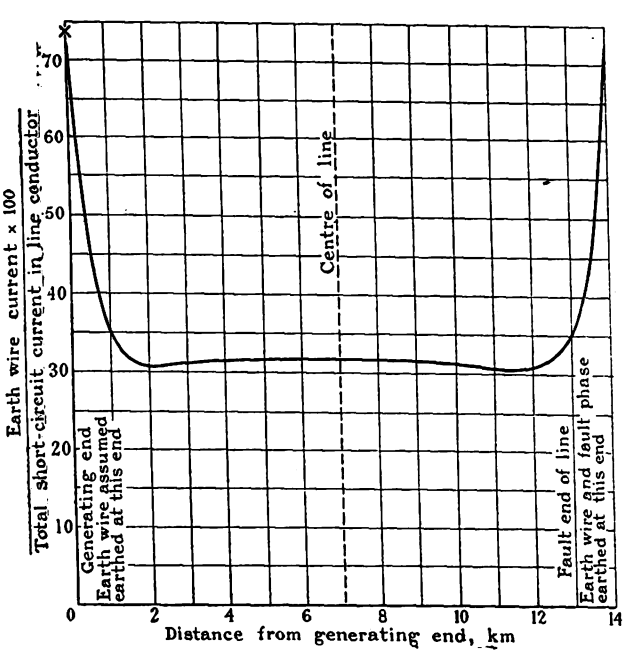


FIG. 9.—Calculated curve showing how the percentage of short-circuit current (in line conductor earthed at 14 km from generating end) flowing in the "earth" wire varies with the distance from generator end on the Bedford–Little Barford "grid" lines. Earth wire earthed at all intermediate towers, which were spaced 900 feet apart. Check point on curve where power measurements were made marked thus ×. For tower dimensions, see Fig. 2.

The most important feature of the "multiple" earthed earth wire from an impedance and interference point of view is that it ensures that there shall be an earth on the earth conductor near the fault wherever the latter may occur on the system.

V. CONCLUSIONS.

(A) POWER LOSSES.

Owing to the well-known fact that the magnitude of the current in a transmission line varies from point to point, the power losses are different from the losses due to the load current alone. The influence of the charging current on the losses is most pronounced when the load current is small or the line very long, but no serious error is involved in neglecting its effects on the "grid" system for lines up to about 50 miles in length and carrying currents above about half full load. Lines of greater length than this which are fed entirely from one end will seldom arise in this country. For such short lines, although the percentage errors in the losses at smaller currents than the above (due to neglecting the line capacitance) become relatively large, yet the losses, being proportional to the square of the R.M.S. currents, are themselves small, so that this is not important.

For practical purposes in this country, the losses (except at very small loads) may therefore be taken as independent of transposition, etc., and dependent only on the R.M.S. value of the load current and the a.c. resistance of the line conductor.

For long lines (regularly transposed) the authors' formula (equation 21) gives the losses directly when the line constants and receiving-end conditions are known.

(B) IMPEDANCE AND INTERFERENCE UNDER NORMAL WORKING CONDITIONS.

Regular transposition of conductors * makes the lines electrically balanced, equalizes the phase impedances and reduces the amount of interference under normal working conditions. It is well known that to obtain the maximum reduction in interference, the points of transposition of the power and communication circuits must be co-ordinated. On single circuit lines transposition involves little, if any, practical difficulty or extra cost and there is *every reason for its general adoption.*

On double circuit lines, transposition involves the use of special "transposition" towers and additional expense and ought, therefore, to be avoided whenever possible. On "long" lines (fed entirely from one end) transposition appears essential, both on account of inductive interference and to avoid large inequalities in the impedance voltage-drop of the conductors. On "short" lines the latter effect may often be negligible compared with the impedance of the transformers and when, in addition, *the interference with communication circuits due to normal* † *operating currents and voltages is also negligible,* transposition is unnecessary.

As already mentioned, lines exceeding about 50 miles in length fed from one end alone, will seldom occur in this country, and for such double circuit lines no definite rules can be laid down regarding transposition. Each case must be judged on its merits with the power and communication authorities in co-operation, the deciding factor being the importance or otherwise of induction from normal operating currents and voltages of the power circuit. Whether transposition is adopted or not, the best results are obtained from the standpoint of operation when the time-phase sequence of currents in the two circuits are co-ordinated. For transposed lines the circuits should be transposed at the same frequency and, to derive the maximum reduction in phase impedance due to mutual inductance between the two power circuits, the time-phase sequence of currents should be such that the top conductor of each circuit carries a current of the same time phase as the bottom conductor of the other circuit (see Figs. 3 (*c*) and 3 (*l*). Under these conditions the two circuits must be transposed in the same direction of spiral.

---

* For double circuit lines, the directions of transposition of the two circuits must be such as to maintain the same relative positions of conductors carrying currents of the same time phase.

† In practice, the effect of transposition on the interference arising under short-circuit conditions is unimportant.

The impedances of the two circuits are then slightly different (unless the outer conductors of each circuit are symmetrical about their middle phase) but in practice the amount of difference is usually so small that a negligible difference in loading occurs with parallel operation. For both circuits the impedances are less than for a single circuit at similar spacings. If the circuits are not transposed the choice of phase sequence lies between that given above which gives minimum impedance, and that in Figs. 3 (*d*) or 3 (*g*), for which conductors in the same horizontal plane have equal impedances, and therefore equal loading of the two circuits takes place with parallel operation. The final choice between the two depends to some extent on the particular spacing, etc., employed. For the "grid" lines the arrangements of Figs. 3 (*c*) and 3 (*l*) are superior to Figs. 3 (*d*) and 3 (*g*), the difference of loading in the former case being unimportant, and the phase impedances, and the differences between them, smaller.

(C) IMPEDANCE AND INTERFERENCE UNDER FAULT CONDITIONS.

Accurate methods are now available for the determination of the short-circuit currents in the line and in the earth under fault conditions both with and without "multiple" earthing of the earth conductor.

When no earth wire is employed, the impedance of the line conductor and earth return is substantially constant all along the line and independent of which phase is earthed or the height of the conductors above earth. This arrangement is disadvantageous from the standpoint of interference, as all the short-circuit current returns via the earth and the voltages induced in earthed conductors of communication circuits are proportional to this current.*

When an earth conductor is employed,† part of the short-circuit current is shunted and the earth current reduced. With the usual construction in which the earth wire is at the top of the towers, the impedance of line and earth (without "multiple" earthing of the earth wire) is still substantially constant all along the line, but now decreases slightly with increasing height of the earthed phase above earth (3 per cent at 50 cycles on the "grid" lines between top and bottom phases). This results in the earth current being slightly less for an earth on the top phase than at the middle or bottom. (For the "grid" lines the maximum difference is 5 per cent at 50 cycles).‡

The percentage of short-circuit current returning through the earth decreases with decrease in impedance of the earth wire, but not in proportion, the reduction obtained falling off rapidly after a certain size of conductor is reached. The reduction obtained also depends upon the relative magnitudes of the impedances of the line and earth and that of the transformers, etc., in circuit with the faulty phase. On the "grid" lines (with the particular steel-cored aluminium conductor to be employed in practice) the earth wire reduces the earth current by between about 18 per cent and 34 per cent, depending on the earth resistivity and the impedance of other apparatus connected to the line. If the cross-section of the wire is increased about 10·5 times, the reduction is only increased about 12 per cent, so that after a certain point the extra reduction in earth current obtained is out of all proportion to the increased cost of the earth conductor.

If a still greater reduction in interference is desired, then it is more economical to employ a second earth wire (suitably positioned below the phase conductors for the "grid" system) than further to increase the cross-section of the first.

On existing American systems the earth wire has in the past usually been made of steel, but this is not the best construction on account of the high a.c. resistance and internal self-inductance of wires of this material.

The best practice is undoubtedly the use of a steel-cored aluminium earth wire, as this meets the requirements of high mechanical strength, high electrical conductivity, and protection from corrosion.

The above conclusions remain, on the whole, unmodified even when the effects of "multiple" earthing of the intermediate towers (between the fault and supply ends of the line) are taken into account, as the percentage of total short-circuit current returning through the earth wire is not materially affected except near the ends of the section under short-circuit. At these points the earth wire current may be a large percentage of the total (viz. 70 per cent in the example in Fig. 9), but it rapidly decreases, as the centre of the section is approached, to the value which would be obtained were the "intermediate" earths absent. Unless the short-circuited section is very short (of the order of 1 or 2 kilometres on the "grid" lines) the reduction in earth current is, on the average, only a few per cent and for practical purposes may be neglected, as this leads to a slight over-estimate of the inductive effects.

From the standpoint of interference the main benefit to be derived from "multiple" earthing is that it ensures the "earth" wire being "earthed" in the immediate vicinity of a fault (to earth) *wherever it occurs on the system*. The whole short-circuit current can then never pass *entirely* through the earth for a distance greater than that from the "fault" to the nearest tower on the return route, and for this reason "multiple" earthing is advocated.

The authors desire to acknowledge indebtedness to Mr. E. B. Wedmore, and to Dr. E. H. Rayner, Dr. A. H. M. Arnold, and Mr. R. O. Kapp for valuable criticism and suggestions received during the preparation of the Report.

---

* Interference due to this cause is obviously unaffected by transposition of the line conductors.

† Assumed earthed at each tower.

‡ Transposition reduces the possibility of any such difference.

INTRODUCTION TO APPENDICES.

The following Appendices give the mathematical theory and methods of calculation of the quantities discussed in the preceding pages. Some experimental data from the authors' tests on the impedance of a line conductor and earth return are also included. Numerical examples for the 132-kV "grid" towers are worked out in detail.

Symbols (Appendix I). Appendix I gives a list of the principal symbols used.

Impedance and Copper Losses (Appendix II). In Appendix II formulæ are derived for the impedance and power loss of a line conductor without earth return, i.e. under normal working conditions.

Impedance with Earth Return (Appendix III). In Appendix III formulæ are deduced for the impedance of a line conductor with a return circuit via the earth alone or via an earth conductor and the earth in parallel. These conditions apply when one phase is accidentally earthed.

Working Formulæ (Appendix IV). Appendix IV gives working formulæ for the impedance of a conductor with or without earth return. The formulæ are applied, in illustration, to the 132-kV "grid" system.

Bibliography (Appendix V).

APPENDIX I.—SYMBOLS.

The following is a list of the principal symbols used:—

A_1 and A_4 are constants defined in Appendix III.

b = outside radius in cm of stranded conductor.

B = induction density in absolute units.

E = electric force in absolute units.

$\Delta E_1, \Delta E_2, \Delta E_3$ = impedance voltage-drops per cm along Phases 1, 2 and 3 when carrying currents I_1, I_2, I_3 respectively.

E_s = sending-end voltage to neutral.

E_r = receiving-end voltage to neutral.

Δe_1 = potential-drop per cm along Phase 1 when carrying a short-circuit current J_1.

Δe = potential-drop in earth when carrying current I_5.

f = frequency in periods per second.

G = leakage conductance per unit length of a short-circuited section of the line, equivalent to the effect of intermediate (or "multiple") earthed towers.

$= R'_i l_0$.

h = height in cm of conductor above earth.

h_1, h_2, h_3, h_4 = heights in cm of phase conductors 1, 2, 3 and earth wire respectively above earth.

H_0 and H_1 = Bessel functions defined in Appendix III.

i = current density in the earth in absolute units.

$I_r = \mathfrak{J}_1 \pm j\mathfrak{J}_2$ = receiving-end current.

I_l = current at distance "l" from receiving end.

I_1, I_2, I_3 = currents in conductors 1, 2 and 3 respectively.

I_4, I_5 = currents in earth wire and earth respectively.

J_1 = short-circuit current in Phase 1.

$K = 2\pi\sqrt{(f/u)}$.

$K_1 = K\sqrt{2}$.

l = length in cm between neutral of generator and point where Phase 1 is earthed.

l_0 = length in cm between consecutive towers.

l_1 = length of line between receiving end and point considered.

L = self-inductance of earth per unit length in absolute units.

L' = inductance of earth plate and fault connection in absolute units.

L_1, L_2, L_3 = self-inductance in henrys per cm to neutral of Phases 1, 2 and 3 respectively.

M = coefficient of mutual inductance between conductors ($M_{1,4}$ indicates the mutual inductance coefficient between the conductors in Positions 1 and 4) in henrys per cm.

R = resistance of earth per unit length in absolute units.

R_K = a.c. resistance in ohm/cm of phase conductors when isolated.[*]

R_{KM} = a.c. resistance in ohm/mile of phase conductors when isolated.

R_{Ka} = a.c. resistance per cm in absolute units of phase conductors when isolated.

R' = a.c. resistance in abohms of earth plate and fault connections at fault towers (or towers).

R'_i = a.c. resistance in abohms of earth plates at intermediate towers (i.e. towers other than those at each end of the short-circuited section).

R_4 = a.c. resistance of earth wire per cm length in abohms when isolated.

R'_4 = a.c. contact resistance of earth wire connections, in abohms.

r_4 = outside radius of earth conductor, cm.

ρ = distance of a point from axis of line conductor, cm.

u = specific resistance of earth in absolute units.

$S_{,1,4}$ etc. = distances in cm between conductors 1 and 4, etc.

t = time co-ordinate.

---

[*] For a non-magnetic conductor the a.c. and d.c. resistance for practical sizes and frequencies, etc., are sensibly equal. This also applies to steel-cored conductors having two oppositely spiralled layers of wires over the cores. For steel conductors or steel-cored conductors with one or three layers over the core, the a.c. resistance may be 25 per cent greater than the d.c. value. See Section III (*c*).

$\omega = 2\pi f$.

γ = Bessel's constant 1·7811. . . .

Y = vector admittance per unit length of line.

$= (g + jc)$, where g = leakage conductance per unit length, and c = capacity susceptance per unit length.

Z = vector impedance per unit length of line.

$= (R_{KM} + jx)$, where R_{KM} = a.c. resistance of isolated conductor per unit length; x = reactance per unit length.

Some additional symbols are defined in appropriate places.

APPENDIX II.—THE RESISTANCE, REACTANCE AND POWER LOSSES ON THREE-PHASE OVERHEAD LINES.

(A) INTRODUCTION.

In this Appendix methods and formulæ are given for evaluating the resistance, reactance and power losses on a three-phase system of overhead lines in any practical configuration of line conductors. Worked numerical examples illustrating the use of the formulæ are given in Appendix V.

(B) ASSUMPTIONS.

Unless otherwise stated, the line conductors are assumed to be solid homogeneous cylinders having unit permeability. The modifications due to stranding iron-cored conductors, etc.,* are pointed out in appropriate places. The conductor currents are assumed to form a "balanced" three-phase system as follows:—

$$\begin{aligned} &\text{Current in conductor 1} = I_1 \\ &\text{Current in conductor 2} = I_2 = I_1 e^{2\pi j/3} = I_1(-0\cdot5 + 0\cdot866j) \\ &\text{Current in conductor 3} = I_3 = I_1 e^{4\pi j/3} = I_1(-0\cdot5 - 0\cdot866j) \end{aligned}$$

A unit length of line is considered in the theory (which in the case of transposed lines contains three transpositions), over which the line current is assumed constant in magnitude. In certain instances on long lines this assumption is not permissible, and these cases are dealt with at the end of the Appendix.

The current in each conductor is taken as returning through an imaginary "neutral" wire parallel to the phase conductors, but situated at a very large distance "l" away. When the currents are balanced, the magnetic effect of this conductor is zero and, as will be seen later, the terms in the formulæ involving "l" cancel out.

(C) SINGLE CIRCUIT TOWERS.

(i) *General theory.*

We shall first consider the case of a tower carrying only one three-phase circuit and in which the conductors are spaced in any irregular configuration (as shown in Fig. 1) and are not transposed. Under such conditions the impedance voltage-drop along each conductor is made up of two parts, one due to the simple a.c. resistance (of an isolated conductor under the conditions assumed) and the other due to combined effects of the self-inductance of the phase considered and of the mutual inductance effects of the other two conductors. Thus an expression for the voltage-drop involves only the conductor currents, the dimensions of the conductors and the geometry of their arrangement. Symbolically, in Phase 1 we have

$$\Delta E_1 = I_1 R_K + j\omega(L_1 I_1 + M_{2,1} I_2 + M_{3,1} I_3) \text{ vector volt/cm} \quad . \; . \; . \; . \; . \; . \; . \quad (1)$$

Similar expressions may be obtained for the other two phases by permuting the suffixes.

The values of the coefficients of self and mutual inductance depend only upon the geometry of the spacing and have the following values:—

$$L_1 = \left(0\cdot5 + 2\,\text{logh}\,\frac{l}{b}\right)10^{-9} \text{ henry per cm} \quad . \; . \; . \; . \; . \; . \; . \quad (2)$$

$$M_{2,1} = \left(2\,\text{logh}\,\frac{l}{S_{1,2}}\right)10^{-9} \text{ henry per cm} \quad . \; . \; . \; . \; . \; . \; . \quad (3)$$

$$M_{3,1} = \left(2\,\text{logh}\,\frac{l}{S_{1,3}}\right)10^{-9} \text{ henry per cm} \quad . \; . \; . \; . \; . \; . \; . \quad (4)$$

Substituting these values in equation (1) and writing I_2 and I_3 in terms of I_1, we have

$$\Delta E_1 = I_1 R_K + j\omega I_1 10^{-9}\left[\left(0\cdot5 + 2\,\text{logh}\,\frac{l}{b}\right) + (-0\cdot5 + 0\cdot866j)\left(2\,\text{logh}\,\frac{l}{S_{1,2}}\right) + (-0\cdot5 - 0\cdot866j)\left(2\,\text{logh}\,\frac{l}{S_{1,3}}\right)\right] \quad . \quad (5)$$

---

* Skin-effect is neglected, as calculation shows the effect is less than 1 per cent in cases of the kind dealt with herein.

Thus the impedance of Phase 1 is given by*

$$\frac{\Delta E_1}{I_1} = R_K + j\omega 10^{-9}\left[\left\{0\cdot 5 + 2\,\text{logh}\,\frac{(S_{1,2}\times S_{1,3})^{\frac{1}{2}}}{b}\right\} - \left(\sqrt{3}j\,\text{logh}\,\frac{S_{1,2}}{S_{1,3}}\right)\right] \quad \ldots \quad (6)$$

$$= \left(R_K + \sqrt{3}\omega 10^{-9}\,\text{logh}\,\frac{S_{1,2}}{S_{1,3}}\right) + j\omega 10^{-9}\left(0\cdot 5 + 2\,\text{logh}\,\frac{(S_{1,2}\,S_{1,3})^{\frac{1}{2}}}{b}\right) \text{ ohm/cm to neutral} \quad \ldots \quad (7a)$$

Similarly,

$$\frac{\Delta E_2}{I_2} = \left(R_K + \sqrt{3}\omega 10^{-9}\,\text{logh}\,\frac{S_{2,3}}{S_{1,2}}\right) + j\omega 10^{-9}\left(0\cdot 5 + 2\,\text{logh}\,\frac{(S_{2,3}\,S_{1,2})^{\frac{1}{2}}}{b}\right) \text{ ohm/cm to neutral} \quad \ldots \quad (7b)$$

$$\frac{\Delta E_3}{I_3} = \left(R_K + \sqrt{3}\omega 10^{-9}\,\text{logh}\,\frac{S_{1,3}}{S_{2,3}}\right) + j\omega 10^{-9}\left(0\cdot 5 + 2\,\text{logh}\,\frac{(S_{1,3}\,S_{2,3})^{\frac{1}{2}}}{b}\right) \text{ ohm/cm to neutral} \quad \ldots \quad (7c)$$

The absolute value of the impedance of Phase 1

$$= 10^{-9}\sqrt{\left[\left(R_K\times 10^{-9} + \sqrt{3}\omega\,\text{logh}\,\frac{S_{1,2}}{S_{1,3}}\right)^2 + \omega^2\left(0\cdot 5 + 2\,\text{logh}\,\frac{(S_{1,2}\,S_{1,3})^{\frac{1}{2}}}{b}\right)^2\right]} \text{ ohm/cm to neutral} \quad . \quad (7d)$$

In equation (7*a*) the term in the first bracket is the apparent resistance and that in the second bracket the reactance to neutral of Phase 1. The term

$$\left(\sqrt{3}\omega 10^{-9}\,\text{logh}\,\frac{S_{1,2}}{S_{1,3}}\right)$$

in the apparent resistance is due to a transference of power between the conductors through the magnetic field. A similar phenomenon has already been noted in connection with three single-conductor cables.† For a given configuration and axial separation of the conductors, the direction of the phase transference depends on the sequence of the currents in the conductors. For example, if the currents in the conductors were in the following sequence:—

$$\text{Phase } 1 = I_1$$
$$\text{Phase } 2 = I_1 e^{4\pi j/3}$$
$$\text{Phase } 3 = I_1 e^{2\pi j/3}$$

then the first term of equation (7*a*) would be

$$\left(R_K + \sqrt{3}\omega 10^{-9}\,\text{logh}\,\frac{S_{1,3}}{S_{1,2}}\right) = \left(R_K - \sqrt{3}\omega 10^{-9}\,\text{logh}\,\frac{S_{1,2}}{S_{1,3}}\right) \quad \ldots \quad (8)$$

The sign of the second term in equations (7*b*) and (7*c*) for the apparent resistance of Phases 2 and 3 would be similarly changed. Again, for a given phase sequence of currents the magnitude and sign of the term

$$\left(\sqrt{3}\omega 10^{-9}\,\text{logh}\,\frac{S_{1,2}}{S_{1,3}}\right)$$

clearly depend on the relative magnitudes of $S_{1,2}$ and $S_{1,3}$. In general, the apparent resistance and reactance in asymmetrical spacing without transposition are different in all three phases.

---

* These three unit voltage-drops are not spaced 120° apart in time phase except in equilateral triangular spacing. The angle between the vector voltage drop of Phase 1 and the Current I_1:—

$$= \text{Arc tan}\,\frac{\text{Apparent Reactance}}{\text{Apparent Resistance}}$$

$$= \text{Arc tan}\left[\frac{\omega\left(0\cdot 5 + 2\,\text{logh}\,\frac{(S_{1,2}\,S_{1,3})^{\frac{1}{2}}}{b}\right)}{10^{-9}R_K + \sqrt{3}\omega\,\text{logh}\,\frac{S_{1,2}}{S_{1,3}}}\right] = \phi \text{ (say)}$$

Angle between vector voltage-drop of Phase 2 and Current I_2:—

$$= \text{Arc tan}\left[\frac{\omega\left(0\cdot 5 + 2\,\text{logh}\,\frac{(S_{2,3}\,S_{1,2})^{\frac{1}{2}}}{b}\right)}{\left(R_K 10^{-9} + \sqrt{3}\omega\,\text{logh}\,\frac{S_{2,3}}{S_{1,2}}\right)}\right] = \theta \text{ (say)}$$

Angle between vector voltage-drops of Phases 1 and 2 = $2\pi/3 + (\theta - \phi)$.

† See Bibliography, Ref. No. 36, page 367. This transference of power does not affect the heating of the conductors which is the same in all conductors and is equal to the square of the absolute value of the current multiplied by R_K. The power transferred to Phase 1 from the other two conductors is:—

$$= \left(\sqrt{3}\omega 10^{-9}\,\text{logh}\,\frac{S_{1,2}}{S_{1,3}}\right) I^2 \text{ watts per cm length} \quad \ldots \quad (7e)$$

where I is the absolute (or measured) value of the current.

(ii) *Effect of symmetry.*

(*a*) *Triangular spacing.*—In equilateral triangular spacing

$$S_{1,2} = S_{1,3} = S_{2,3}$$

Thus, both with or without transposition, equation (7*a*) becomes

$$\frac{\Delta E_1}{I_1} = R_K + j\omega 10^{-9}\left(0\cdot5 + 2 \operatorname{logh}\frac{S_{1,2}}{b}\right) \text{ ohm/cm to neutral} \quad \ldots \ldots \quad (9a)$$

$$= (0\cdot161 \times 10^6 R_K) + j\left(0\cdot0253 + 0\cdot233 \log_{10}\frac{S_{1,2}}{b}\right) \text{ ohm/mile to neutral at 50 cycles} \quad \ldots \quad (9b)$$

Under such conditions the numerical values of the resistance and reactance are equal in all three phases, though vectorially the voltage-drops are 120° apart in phase.

(*b*) *Transposition.*—If the conductors are regularly transposed, the above-mentioned effects of asymmetry balance out over an integral multiple of three transpositions.* The resistance of any phase will then be R_K and the reactance will be the average of the values in equations (7*a*), (7*b*) and (7*c*); that is,

$$\text{Vector reactance per phase} = j\omega 10^{-9}\left(0\cdot5 + 2 \operatorname{logh}\frac{(S_{1,2} \times S_{1,3} \times S_{2,3})^{\frac{1}{3}}}{b}\right) \text{ ohm/cm to neutral} \quad . \quad (10a)$$

Numerically,

$$\text{Reactance per phase} = 0\cdot0253 + 0\cdot233 \log_{10}\frac{(S_{1,2} \times S_{1,3} \times S_{2,3})^{\frac{1}{3}}}{b} \text{ ohm/mile to neutral at } 50 \sim \quad . \quad (10b)$$

(D) DOUBLE CIRCUIT TOWERS.

(i) *General considerations.*

In the following treatment it is assumed that the conductors of each circuit are asymmetrically spaced, but that the two circuits are symmetrically arranged about the vertical centre line of the tower. The loads on the two circuits are assumed to be equal and separately balanced. When neither circuit is transposed, there are then six ways of permuting the time phase of the currents in one circuit for a given time-phase sequence of currents in the other (see Figs. 3 (*a*), (*b*), (*c*), (*d*), (*e*), (*f*)); while if the currents in both circuits are permuted, there are twelve possible arrangements (see Figs. 3 (*a*) to 3 (*l*)).† There are, however, only thirty-six different impedance equations for all the conductors for the reasons given below. In ten of the arrangements, each involving six impedance equations, five involve the same thirty equations as the other five, the only difference being that the values for the two circuits are interchanged. Corresponding arrangements are Figs. 3 (*a*) and 3 (*j*), 3 (*b*) and 3 (*k*), 3 (*c*) and 3 (*l*), 3 (*e*) and 3 (*f*), 3 (*h*) and 3 (*i*).

In addition, for Figs. 3 (*d*) and 3 (*g*), we shall show later that the three impedance equations of each circuit are equal in each figure (though the three equations of Fig. 3 (*d*) are different from those of Fig. 3 (*g*)). Thus, as in the other ten arrangements, there are only half as many impedance equations as conductor positions.

In the following sub-section a simple rule is deduced by which the impedance in any arrangement may be written down directly, and a discussion is given of the characteristics of the various arrangements both with and without transposition.

(ii) *Derivation of impedance equations* (*conductors not transposed*).

Take as a typical example the sequence of currents shown in Fig. 3 (*l*).
Let

$$\text{Current in conductor Position 1} = \text{current in conductor Position 4} = I_1$$

$$\text{Current in conductor Position 2} = \text{current in conductor Position 5} = I_2 = I_1 e^{2\pi j/3}$$

$$\text{Current in conductor Position 3} = \text{current in conductor Position 6} = I_3 = I_1 e^{4\pi j/3}$$

---

[*] Regular transposition makes the voltage-drop vectors 120° apart in phase.

[†] It may be noted that in any of the 12 arrangements the phase impedances remain unaltered if the time phase of *all* the currents is altered by, say, $2\pi/3$ or $4\pi/3$.

The voltage-drop per unit length along any conductor is equal to the sum of the drop due to the simple a.c. resistance of an isolated conductor and a reactance-drop due to the self-inductance of the conductor considered and five mutual inductance effects due to the other five conductors. Thus the voltage-drop along the conductor in Position 1,

$$\Delta E_1 = I_1 R_K + j\omega(L_1 I_1 + M_{2,1} I_2 + M_{3,1} I_3 + M_{4,1} I_1 + M_{5,1} I_2 + M_{6,1} I_3) \text{ vector volts/cm} \quad . \quad . \quad (11)$$

$$= I_1 R_K + j\omega I_1(L_1 + M_{4,1}) + I_2(M_{2,1} + M_{5,1}) + I_3(M_{3,1} + M_{6,1}) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (12)$$

Writing I_2 and I_3 in terms of I_1 and putting

$$M_{4,1} = \left(2 \operatorname{logh} \frac{l}{S_{4,1}}\right)10^{-9}$$

$$M_{5,1} = \left(2 \operatorname{logh} \frac{l}{S_{5,1}}\right)10^{-9}$$

$$M_{6,1} = \left(2 \operatorname{logh} \frac{l}{S_{6,1}}\right)10^{-9}$$

the vector impedance of Phase 1,

$$\frac{\Delta E_1}{I_1} = R_K + j\omega 10^{-9}\left(0 \cdot 5 + 2 \operatorname{logh} \frac{(S_{2,1}\, S_{3,1}\, S_{5,1}\, S_{6,1})^{\frac{1}{4}}}{b S_{4,1}} + \sqrt{3} j \operatorname{logh} \frac{S_{3,1}\, S_{6,1}}{S_{2,1}\, S_{5,1}}\right) \text{ ohm/cm to neutral} \quad . \quad . \quad . \quad (13)$$

$$= \left(R_K + \sqrt{3}\omega 10^{-9} \operatorname{logh} \frac{S_{2,1}\, S_{5,1}}{S_{3,1}\, S_{6,1}}\right) + j\omega 10^{-9}\left(0 \cdot 5 + 2 \operatorname{logh} \frac{(S_{2,1}\, S_{3,1}\, S_{5,1}\, S_{6,1})^{\frac{1}{4}}}{b S_{4,1}}\right) \text{ ohm/cm to neutral} \quad . \quad (14a)$$

$$= (P_1 + jQ_1), \text{ say.}$$

From this equation we see that the *apparent resistance* of any conductor is equal to

$$\left[R_K + \sqrt{3}\omega 10^{-9} \operatorname{logh} \frac{\text{(Product of axial distances from conductor to other two carrying current } 2\pi/3 \text{ later in time phase)}}{\text{(Product of axial distances from conductor to two others carrying current } 4\pi/3 \text{ later in time phase)}}\right] \text{ ohm/cm}$$

Similarly, the *apparent reactance* is equal to

$$j\omega 10^{-9}\left[0 \cdot 5 + 2 \operatorname{logh} \frac{\text{(Product of axial distances from conductor considered to four others carrying current of different time phase)}^{\frac{1}{4}}}{(b \times \text{axial distance from conductor considered to other carrying current of same time phase)}}\right] \text{ ohm/cm to neutral.}$$

Using these two rules, we may write directly the impedances of the remaining five conductors in Fig. 3 (*l*) as follows:—

$$\frac{\Delta E_2}{I_2} = \left(R_K + \sqrt{3}\omega 10^{-9} \operatorname{logh} \frac{S_{3,2}\, S_{6,2}}{S_{1,2}\, S_{4,2}}\right) + j\omega 10^{-9}\left(0 \cdot 5 + 2 \operatorname{logh} \frac{(S_{1,2}\, S_{3,2}\, S_{4,2}\, S_{6,2})^{\frac{1}{4}}}{b S_{5,2}}\right) \text{ ohm/cm to neutral} \quad . \quad (14b)$$

$$= (P_2 + jQ_2), \text{ say.}$$

$$\frac{\Delta E_3}{I_3} = \left(R_K + \sqrt{3}\omega 10^{-9} \operatorname{logh} \frac{S_{1,3}\, S_{4,3}}{S_{2,3}\, S_{5,3}}\right) + j\omega 10^{-9}\left(0 \cdot 5 + 2 \operatorname{logh} \frac{(S_{1,3}\, S_{2,3}\, S_{4,3}\, S_{5,3})^{\frac{1}{4}}}{b S_{6,3}}\right) \text{ ohm/cm to neutral}^* \quad . \quad (14c)$$

$$= (P_3 + jQ_3), \text{ say.}$$

$$\frac{\Delta E_4}{I_4} = \left[\left(R_K + \sqrt{3}\omega 10^{-9} \operatorname{logh} \frac{S_{2,4}\, S_{5,4}}{S_{3,4}\, S_{6,4}}\right) + j\omega 10^{-9}\left(0 \cdot 5 + 2 \operatorname{logh} \frac{(S_{2,4}\, S_{3,4}\, S_{5,4}\, S_{6,4})^{\frac{1}{4}}}{b S_{1,4}}\right)\right] \text{ ohm/cm to neutral} \quad (14d)$$

$$\frac{\Delta E_5}{I_5} = \left[\left(R_K + \sqrt{3}\omega 10^{-9} \operatorname{logh} \frac{S_{3,5}\, S_{6,5}}{S_{1,5}\, S_{4,5}}\right) + j\omega 10^{-9}\left(0 \cdot 5 + 2 \operatorname{logh} \frac{(S_{1,5}\, S_{3,5}\, S_{4,5}\, S_{6,5})^{\frac{1}{4}}}{b S_{2,5}}\right)\right] \text{ ohm/cm to neutral} \quad (14e)$$

$$\frac{\Delta E_6}{I_6} = \left[\left(R_K + \sqrt{3}\omega 10^{-9} \operatorname{logh} \frac{S_{1,6}\, S_{4,6}}{S_{2,6}\, S_{5,6}}\right) + j\omega 10^{-9}\left(0 \cdot 5 + 2 \operatorname{logh} \frac{(S_{1,6}\, S_{2,6}\, S_{4,6}\, S_{5,6})^{\frac{1}{4}}}{b S_{3,6}}\right)\right] \text{ ohm/cm to neutral} \quad (14f)$$

---

* These vector voltage-drops are not 120° apart in phase.

The angle between the voltage-drops of Phases 1 and 2 $= \frac{2\pi}{3} + \left(\text{arc tan} \frac{Q_1}{P_2} - \text{arc tan} \frac{Q_2}{P_2}\right)$

Angle between voltage-drops of Phases 2 and 3 $= \frac{2\pi}{3} + \left(\text{arc tan} \frac{Q_2}{P_2} - \text{arc tan} \frac{Q_3}{P_3}\right)$

Numerical value of impedance of Phase 1 $= \sqrt{(P_1^2 + Q_1^2)}$ ohm per cm

In the particular case when the two outers of each circuit are symmetrical about their middle phase conductors

(i.e. $S_{1,4} = S_{6,3}$; $S_{5,1} = S_{6,2} = S_{4,2} = S_{5,3}$; $S_{1,2} = S_{6,5} = S_{2,3} = S_{5,4}$; $S_{1,3} = S_{6,4}$; $S_{1,6} = S_{3,6}$),

the above expressions become

$$\frac{\Delta E_1}{I_1} = \frac{\Delta E_4}{I_4}$$

as in equation (14*a*).

$$\frac{\Delta E_2}{I_2} = \frac{\Delta E_5}{I_5} = R_K + j\omega 10^{-9}\left(0\cdot 5 + 2\,\mathrm{logh}\,\frac{S_{1,2}\,S_{4,2}}{bS_{5,2}}\right) \quad . \; . \; . \; . \; . \; . \; . \; . \quad (14g)$$
